ORIGINAL ARTICLES.

FIVE CASES OF SUDDEN DEATH DUE TO ASCENDING NEURITIS.

BY J. FERGUSON, A.M., M.D., L.R.C.P.,
OF TORONTO, CANADA;
DEMONSTRATOR OF ANATOMY, UNIVERSITY OF TORONTO, MEDICAL FACULTY; LECTURER ON NERVOUS DISEASES, SUMMER SESSION.

ONE of the very unpleasant experiences to which all physicians are from time to time subjected is the sudden and unexpected death of a patient. As I have had my share of this sort of humiliation, it may not be quite out of place to make a few remarks on some of my cases for the perusal, and perhaps benefit, of others. A number of examples of sudden death after diphtheria I have already published—some in the *Canadian Practitioner* and some in THE MEDICAL NEWS. The cases I now propose relating were in adult patients, in whom it was quite impossible to anticipate a sudden and fatal termination. It is in this mainly that their interest rests.

CASE I.—This patient was a married lady, aged thirty years. In September, 1890, she thought she caught cold in her legs, and as a consequence had some rheumatic pains and tenderness. There was a gradual loss of power below the knees. The muscles in the tibio-fibular regions atrophied a good deal, and gave to the electric test the reaction of degeneration. The feet and toes dropped to an increasing degree. The pain was at times very great. The condition steadily ascended so as to involve the muscles in the back of the thighs. The muscles supplied by the anterior crural nerve escaped; and on the day of the patient's death the patellar reflex was good, and the patient had the power of extending the leg upon the thigh, and flexing the thigh upon the pelvis. There was no loss of control over the bladder or rectum.

Shortly after the symptoms began in the legs, there were ill-defined pains in the arms, and a loss of power. These conditions increased, until the pain became almost unendurable; and the motor loss was very pronounced. There was the reaction of degeneration, rapid wasting of muscles, and extreme tenderness on pressure. Throughout the progress of the case, till the last day, there was no evidence of any cord-affection.

On making a visit one afternoon early in November, I found the pulse very rapid, at least 150 per minute, weak and irregular. The woman complained of faintness and difficulty in breathing. In the evening, about 8 o'clock, while attempting to raise her head for a drink, she rolled over and immediately died.

What was the cause of this sudden termination of the case? It may be well here to note that the paralysis in the arms was clinically of an ascending character. The hands first became affected, then the forearms, and finally the arms and the deltoids. I think the case one of peripheral ascending neuritis; and that, as the disease ascended, the brachial plexus became involved. According to the researches of Gaskell and others, the results of which I have been able to confirm, the spinal nerves going to the heart come from the fifth, sixth, seventh, and eighth cervical, and the first, but mainly the second, dorsal nerves. These roots pass into the second and thir cervical sympathetic ganglia, and thence by the cardiac splanchnics to the heart. I think we are here on the threshold of an important truth. The inflammation had ascended the nerves of the arm to the plexus, and then involved the spinal nerves for the heart; hence the sudden death in a case in which the heart was free from disease. In this case there was no history of any form of chronic poisoning by lead or arsenic, and the patient was very temperate in her habits. Syphilis was also thoroughly excluded.

It may be well to call attention to the violent axillary pains and arm-pains felt in cases of angina pectoris. The true explanation is no doubt to be found in the origin of spinal cardiac nerves from the same roots as form the brachial plexus. In one case of angina of which I know there is most excruciating pain along the inner side of the arm to the little finger; and another severe pain along the course of the second dorsal nerve, the one from which, according to Gaskell, the main cardiac root springs. Just so, in reverse order, in the case of ascending neuritis, the origin of the cardiac nerves is reached, and the vital springs of life are thus touched unexpectedly by an unseen hand, and the patient is thus hurriedly carred off.

In my case I cannot verify this diagnosis by a post-mortem examination, yet I think the clinical history, showing the existence of a neuritis, is so clear that this must be taken as proved.

CASE II.—This case is unique in several respects. The patient, a female, was in her forty-third year. In February, 1890, she had an attack of influenza, from which she never fully recovered. From the

date of this attack she had paroxysms of pain in the abdominal viscera of a most dreadful character. She would writhe and sweat in these attacks of pain. It must be borne in mind that she was somewhat excitable, and to some extent may have exaggerated her sufferings; but there was real distress. The pain was described as grinding, burning, boring, twisting, or piercing. These attacks were almost regularly periodic, usually having their acme toward morning.

The list of anodynes, analgesics, and antiperiodics was exhausted; and it was often a wish that there were not some more to try, if for no other reason than to show that the therapeutic armamentarium had not been wholly depleted. Any relief that came from treatment was of a very temporary character. On making use of some new agent there would appear to be some real or fancied benefit for a short time. The patient lost weight and strength. At no time, after the recovery from influenza, was there any appreciable amount of fever, the thermometer ranging from normal to 100° F., the latter point, however, being very seldom reached. All of the reflexes, superficial and deep, were normal. The pulse was never rapid, unless the patient was excited or had made some exertion. Constipation was very troublesome, and this fact is of some importance in the case, as throwing some light upon it. All are familiar with the constipation that annoys patients suffering from paraplegia. We also know that if a nerve is injured the muscles supplied by it atrophy. The sympathetic is the nerve-supply to the intestinal walls. It is true that the nerves entering the intestines are a mixture of sympathetic and cerebro-spinal, and any disease or lesion of the sympathetic would thus cut off the intestines from the cord, producing the same results as if the cord itself were the seat of the lesion. The roots passing into the sympathetic from the cord are both motor and sensory. In the case of locomotor ataxia, the violent lightning-pains in the legs are due to the fact that the posterior sensory spinal roots are involved, and not merely to the fact that the fasciculi cuneati are diseased. So in the case under consideration. The disease in the sympathetic nerves must involve the spinal fibers in them, and as these latter are motor and sensory, there will consequently be sensory symptoms.

The pulse was good throughout the attack, and remained so till the day prior to death. The afternoon before the patient died she was out driving for a short time, as, for a few days, she had been easier than usual. During the forenoon of the following day she complained of her heart fluttering a great deal, and there was some difficulty in breathing. She appeared pale and haggard. At noon she partook of some light nourishment, and then had her wrapper put on and sat in the easy-chair for about an hour. She became very quiet, and in a few minutes fainted away and died.

How can we explain this sudden death? The post-mortem examination revealed the condition of a neuritis distributed through the abdominal cavity. The sympathetic ganglia were congested, and the visceral nerves inflamed and degenerated. The microscopic examination, made with great care, revealed the fact that the nerve-tissue was undergoing marked changes of a degenerative character, such as are met with in neuritis. This neuritic and degenerative process had been gradually going on, and ascending until the roots were reached that go to form the cardiac splanchnics. When this happened, the patient suddenly died of cardiac failure, from lack of cardiac innervation. The examination of the muscular tissue of the intestines showed atrophy, in some places very marked, similar to that found in an ordinary muscle that had been cut off from its motor nerve supply. In the foregoing pathologic anatomy we have a clear explanation of the pain, the constipation, and the sudden death. Some may object, and say that if the nerves were inflamed the pain ought to have been constant. Such was the case with the violent periodic attacks already mentioned. Cases of sciatica and trigeminal neuralgia are met with, in which the pain is markedly periodic, and yet the underlying condition is clearly a neuritis.

Case III.—This case is one of very great interest on account of the direct nature of the evidence of the existence of an ascending neuritis. An elderly lady of sixty-seven years had the left axilla cleaned out for a malignant neoplasm, extending from the breast, that had been removed some months previously. The operation was very difficult, as the enlarged glands were adherent to every tissue. The nerves in the axilla were no doubt considerably injured. There developed after the operation a very severe neuralgia of several of the branches of the brachial plexus, but mainly of the ulnar and cutaneous divisions. This began about three weeks after the operation. The wound was carefully treated antiseptically, and healed kindly. In spite of all efforts to control it, the neuralgia increased steadily for two weeks. There was atrophy of the muscles supplied by the ulnar nerve, and some paresis and anesthesia over the areas supplied by the nerves named. Clinically, the symptoms were such as would justify the diagnosis of neuritis.

One morning, at about 10 o'clock, as the patient was making some exertion in dressing herself, she was taken with a violent attack of palpitation, and had to be helped to bed. I saw her two hours after the attack of palpitation began. When I made an examination of the heart it was then beating only thirty-two times a minute. Stimulants and restoratives were freely tried, but to no purpose, as the patient sank with great rapidity, and died within half an hour of my arrival.

The nerves of the affected side were examined. The spinal roots from the sixth cervical to the second dorsal were found inflamed. Here I think we have an explanation for the sudden death. The injured nerves in the axilla became inflamed, and this set up the process of an ascending neuritis,

which in time reached the roots of the spinal nerves, and then, as already explained, involved the spinal nerve-supply passing to the heart. The heart itself was quite normal, and presented no conditions that could in any way account for the suddenly fatal termination of the case. To one who does not wish to be hypercritical, it seems that the evidence is sufficient in this case to justify the opinion that the neuritis in the axillary nerves was caused by the operation; that this neuritis pursued an ascending course; that it finally reached the spinal origin of the cardiac nerves; and that this caused the great attack of palpitation, followed by the marked reduction of the number of heart-beats till they ceased altogether.

CASE IV.—This case is not so direct in its proof as the others; and yet there is good evidence for regarding it as one of ascending neuritis, ultimately reaching the cardiac nerves. The patient was forty-three years of age, and had had her left breast removed for carcinoma. At the time of the operation all the axillary glands were removed. The wound healed well, the patient being up and around in two weeks from the date of the operation. There was not the slightest evidence of any form of cardiac disease at the time of the operation, or at any subsequent time. I frequently saw the patient from the date of the operation till the time of her sudden death, and on no occasion was there the least symptom of heart-trouble. About three weeks before her death I was consulted for pains and numbness extending along the inner side of the arm and forearm. The nerves mainly affected were the ulnar, the internal cutaneous, the nerve of Wrisberg, and some of the intercostals. There was marked paresthesia over the regions supplied by these nerves. There was pain along their course, and some tenderness on pressure. Three days before death there was discovered a loss of faradic irritability in the muscles supplied by the ulnar nerve. During the night preceding her death she had severe pain in the region of the brachial plexus, with migrating pains in the neck. In the morning she felt unrested, and remained in bed for some time. When alone she made an attempt to get up and dress. When she had about half her clothes on she fell on the floor. Her servant ran up-stairs, and found her lying in an apparent faint. I was telephoned for, but before I got to the house, only a short distance, she had expired.

I did not secure a post-mortem examination, and it is here that the case lacks some of the directness in support of the view that death was due to an ascending neuritis. We have, however, clear clinical evidence of the existence of neuritis involving the ulnar, internal cutaneous, and some other branches of the brachial plexus; and we have also every reason for regarding the heart as free from any form of organic or functional disturbance that could afford an explanation of the very sudden and unexpected death. She was a lady in good circumstances, having every comfort, and without the slightest anxiety or mental worry about anything. Knowing the fact that sudden death may take place in cases of neuritis when the cardiac nerves become involved, there is reason for regarding this as the cause in the present case, corroborated to a very great extent by the entire absence during life of any sign or symptom of disease of the heart.

CASE V.—This was the case of a married lady who was in her twenty-fourth year at the time of her death. She had been married three years, and during this period had been pregnant only once, when she miscarried in the fourth month, and six months after marriage. She menstruated only once after the miscarriage. She had ceased menstruating for over two years at the date of her death. She was spare in flesh, but very active and enjoyed good health. In June she was taken with a very severe attack of diphtheria, from which she recovered. In the middle of September she was exposed and became wet and chilled. On the third day after this I was sent to see her on account of numbness and loss of power in the hand. She complained of marked "pins and needles" sensation in them, while the muscle-power was not more than half of the normal state. The heart was examined and found normal, the beats being full and strong. The palatine and laryngeal muscles were quite free from paresis. There was no numbness or paresthesia in the areas of distribution of any of the cranial nerves. The condition of the arms rapidly grew worse, and the loss of sensation and the paralysis became complete by the end of the first week. The woman died very suddenly on the eleventh day of her illness, with symptoms of syncope or acute heart-failure. Up to the very last the laryngeal and pharyngeal muscles retained their tone, and there was no difficulty in speech or deglutition. It was noticed on the day of her death that there were no abdominal movements during respiration—a fact most likely due to paralysis of the diaphragm, as the abdominal muscles themselves were not involved. Examination of some of the branches of the brachial plexus revealed the existence of neuritis. This began in the hands, and rapidly extended up the arms, taking in one group of muscles after another, till the origin of the cardiac roots was reached, and the splanchnics going to this organ lost their energy over the heart-muscle, when it ceased in the condition of diastole.

The foregoing cases are very interesting. The notes of them cover a considerable time, and are now collected together in the form of a short paper, hoping that it may prove of some interest and elicit from others any further cases of this important condition. It must not be thought, however, that these cases are advanced as a basis for a theory to explain all cases of sudden death due to cardiac failure. In a very able paper by Prof. John A. McWilliam, in the *British Medical Journal* for January, 1889, it

is stated that some cases of sudden heart-failure are due to a condition of fibrillar contraction or twitching in the heart-muscle. In this view I think Prof. McWilliam is quite correct. I found the same condition produced in a number of the animals I experimented upon in the year 1883 (a report of which was published in the *Canadian Practitioner* for August of that year), in reference to the circulation in the coronary arteries. One of the early symptoms of nerve-degeneration is muscle-degeneration, which is revealed by fibrillar contractions and twitchings. In the case of neuritis involving the cardiac nerves, this same condition of muscular degeneration would occur, and hence there would be a ready explanation for such movements in the heart-muscle as we find so ably delineated in Mc William's paper.

FIFTEEN YEARS' OBSERVATION AMONG BEER-DRINKERS.

By LAMBERT OTT, M.D.,
OF PHILADELPHIA.

The manufacture of beer requires the laboring brewer to expose himself to various temperatures ranging from 90° F. to a cold and damp cellar at the freezing-point, although it is not often that one man works in different departments in one day, the members of each gang usually having more or less continuous work at one job, to which they are confined by reason of their experience and training.

It may happen that one man, passing from the "brew-house" through the fermenting-room, thence through the beer storage rooms, cooled by an ice-machine, passes through a varying temperature having the extremes of 100° F. and freezing. In a healthy young adult, not undermined by excesses, and protected by ample clothing, no untoward results follow.

The majority of laborers in a brewery are Germans, with a sprinkling of Irish and a few Americans. The German brewer is by nature an honest, industrious, and good-natured individual, fond of his home and family, and in every way a congenial person; even the Irish and Ameriean brewer partakes of those kind and congenial elements so common to the German brewer, leading one to believe that the constant association and use of beer as a beverage begets a distinctive type of humanity, possessing natures kind and pleasing. The physical peculiarities are a florid complexion, due in many cases to capillary varicosity, and a tendency to the accumulation of fat. Often have I observed young men, of slight build, with no inherited predisposition to obesity, after a year or two in a brewery, acquire a sunny disposition and an accumulation of fat, the attenuated and introspective dyspeptic being transformed into the happy and fat brewer. In rare cases idiosyncrasies are apparent, in which a small and bony individual refuses to acquire fat, even after excessive libations of beer. It is not easy to explain this difference, but those possessing this peculiarity are of a vicious inherited tendency, carrying a diathesis which at an opportune time develops some irremediable ill.

The blood of the beer-drinker—I use the term as applied to men constantly employed in breweries, and drink nothing but beer—shows microscopically an increased proportion of red corpuscles and a diminution of white corpuscles. An inveterate beer-drinker, suddenly ceasing his drinking, suffers no special inconvenience beyond the natural longing, which is of short duration, besides a rapid loss of flesh—I should say redundant flesh—a decline of his florid color, which is soon replaced by a paler hue, but at no time approaching the pallor of anemia. Those consuming large quantities of beer daily, and eating very little food, after a time become stupid, dull to their surroundings, and only aroused from this semi-drowsiness by a fit of anger or an exciting incident; but this mental torpor is only temporary, disappearing as soon as the habit is corrected. When an abnormal condition is caused by excessive beer-drinking, the sudden abstention does not prevent a rapid return to the norm, this fact standing in marked contrast to what occurs to the whiskey-drinker.

I have to differ with the opinion of some writers on stomach-diseases that beer retards digestion, notably Osler, in his recent *Practice*, who otherwise is so clean-cut and select in his therapeutics. The Germans consume three and four large glasses of beer daily with their luncheon or dinner, and I have never yet heard or seen complaints of indigestion, whereas with the use of other alcoholic potations during meals it is different. I have examined the vomit of the whiskey-drinker after having been in the stomach five or six hours, and no indication of chymification of the ingested food was evident. Another peculiarity of the beer-drinker is the enormous bladder-capacity he acquires, passing at one time as much as one quart or more of urine. Stone in the bladder and cystic diseases are exceedingly rare.

Among the pathologic conditions produced by excessive libations of beer, foremost is *subacute gastritis*. This disease is most prevalent in the summer months. Among one hundred cases noted, seventy-eight occurred during the months of June, July, and August. The cause is the pouring of cold beer into an empty stomach; but I have observed this important point, that those suffering from gastric trouble, for the most part, took their morning "Schnapps,"

with a half-dozen drinks interspersed between their drinks of beer. Those confining their drinking entirely to beer suffer less, especially when taking their beverage after or during a meal, and in warm weather avoiding large draughts of cold beer when overheated or into an empty stomach.

The few prominent and ever-present symptoms of this variety of subacute gastritis are: great lassitude, total loss of appetite, vomiting of all food, vomiting of mucus mixed with bile, particularly in the morning; heavy, dull pain in the epigastrium, and a swollen, beefy tongue, with highly red edges. These patients, further, complain of weakness, headache, nausea when smelling cooking, seldom fever, rarely a sub lingual temperature of 100° F., tenderness over the stomach, relaxation of the bowels, profuse perspiration on slight exertion, and palpitation of the heart. There is extreme nervousness, sometimes sleeplessness, and, what is peculiar, an aversion to all drinks. The urine is scanty, high-colored, and shows a heavy deposit of urates. There is one symptom in particular which the brewer complains of when visiting your office, and that is great lassitude. If on further inquiry you find no fever and an aversion to food, one can invariably conclude the case to be one of subacute gastritis. Often there is complaint of such complete prostration and an expression of a fear of typhoid fever developing; but the trouble is gastric and of short duration. The absence of pyrexia at once excludes a continued fever. The duration of the attack is from three to seven days, much depending upon the care the patient takes of himself.

The prognosis is favorable.

In treatment absolute rest in bed is to be insisted upon, with total abstinence from all stimulating drinks; liquid and easily digested diet, including hot milk, hot barley-water and rice-water, beef-tea, hot soups, etc., is to be ordered; and when hot drinks are objectionable cold drinks may be permitted. Milk should be taken with care, slowly sipped, and holding a quantity in the mouth before swallowing; otherwise in most cases it curdles and is rejected. Counter-irritation by means of an application of mustard to the stomach until the skin is permanently reddened is also useful, and the internal administration of the following prescription, in conjunction with the foregoing regimen, I have found a specific:

R.—Bismuthi subnit. . . . . ʒvj.
Sodii bicarb. . . . . ʒj.
M. et div. in chart. no. xij.
Sig.—One powder every two or three hours, preferably on an empty stomach.

For the aggravated thirst I order Vichy or Seltzer water alone, or in case of decided weakness, with equal parts of Rhine or claret wine. In from three to five days convalescence sets in, as evidenced by the return of the appetite, cleaning of the tongue, and a disappearance of the weakness; at this time it is all-important to forbid any malt or spirituous liquors, even a small potation causing an exasperating relapse.

Among two hundred brewers examined as to the condition of the bowels, relaxation was the rule; from two to four bowel-movements daily being the average, which they consider normal. Constipation is rare.

Diseases of the lungs and heart seem uninfluenced by excessive libations of beer. The kidneys are rendered active; the urine passed is light in color, of a low specific gravity, and profuse in quantity. Cirrhotic kidney and hob-nail liver, so common in the whiskey-drinker, *are not found in the beer-drinker.*

In eighty cases of acute alcoholism and delirium tremens occurring in laborers in breweries 75 per cent. were consuming from six to eight drinks of whiskey or brandy in addition to their beer. Cases of delirium tremens were usually heavy beer-drinkers with occasionally "Schnapps," who by and by found too little stimulation in beer, cast it aside and drank stronger alcoholic liquor altogether, until the direst results followed. It is seldom that one finds a pure beer-drinker affected with delirium tremens; oftener acute alcoholism is encountered, and in these cases there is an additional element, as bad home-surroundings or a vicious taint of the system.

I have had under observation a few brewers, rather laborers in a brewery, for fifteen years who drank on an average from twenty-five to fifty glasses of beer daily, in the aggregate from one to two gallons for each sixteen or eighteen hours, and at no time have they been ill or suffered any of the evil consequences of excessive libations. None drank anything but beer, using no tobacco and eating three hearty and well-prepared meals a day. Otherwise they were of good habits, obtaining ample sleep, cleanly, and of a favorable family history. They are yet strong, and capable of great labor. Others living under similar conditions, accustomed to the mixing of their drinks, excessive use of tobacco, have long ago fallen by the wayside.

Many brewers have a vicious habit of drinking numerous glasses of beer before breakfast, and when such a one returns to his home for breakfast at six or seven in the morning his appetite is impaired. The sudden withdrawal of beer in a simple beer-drinker does not produce the violent nerve-agitation that occurs under the same conditions in the whiskey-drinker. He frets and longs for his beverage, but, soon used to abstinence, eats more heartily, becomes paler, and at no time is there marked irritability or peevishness.

Beer taken in moderate quantities under physio-

logic conditions produces plethora—a decided increase of red corpuscles; therefore, in anemia and impaired nutrition, I have found from one to two pints daily, taken with or after meals, or with a light lunch between meals, of decided benefit.

In the foregoing conditions I have, in conjunction with beer, given the tincture of the chlorid of iron, and especially have the results been striking in nursing women, in whom not alone was there an increase in the mammary flow but a richer milk and an improved appearance of the suckling. In a series of experiments I have given plain beer to a number of nursing women and then added iron in an equal number; comparative observations showed that there was in the latter number not only an improvement in the mother's milk, but also in the mother and in the nursling. In women debilitated by protracted nursing and in whom it seemed necessary to wean their babies in the early part of the summer, this treatment has made it possible to prolong the nursing through the hot months and has kept the mother in a fair condition, by reason of which she was able to secrete ample milk and give her child proper care. There is a quantitative and qualitative change in the milk, besides an improved condition of the mother. The quantity taken should be one pint per day for the first week, then two or more pints per day during the nursing period, with fifteen drops of the tincture of ferric chlorid to each pint of beer. Some women unused to beer find difficulty in taking this quantity, despite their intense eagerness to feed their young, but by icing it and drinking during meals tolerance and taste are acquired.

In the puerpera, when on the fifth or sixth day there seems to be a tardy flow of milk, I have ordered this treatment with advantage; and as late as the tenth day, when all hope of obtaining breast-milk had been abandoned, the beer was pushed, and, conjoined with the stimulating effect of the infant nursing, led to the secretion of a satisfactory supply of milk. In very fat women everything fails to stimulate the flow of milk, even a temporary increase due to the beer declining in a few days.

CLINICAL LESSONS.

Notes on Surface-Temperatures as Affected by Posture of Limbs.

By S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND DISPENSARY FOR NERVOUS DISEASES, PHILADELPHIA.

I REMINDED you last winter of the endless possibilities open to mere observation in clinical medicine, when pointing out the peculiarities of local temperatures in a case of erythomelalgia.

To become sure as to general temperatures in a case of disease is usually easy, requiring only ordinary care and good thermometers. But to get surface-temperatures accurately is a more difficult matter, demanding, as it does, more time, far greater care, and instruments that as yet are very unsatisfactory, either because they are too slow in registering, or too fragile. I commonly employ the coil-bulb thermometer, guarding the coil with a cork, hollowed so as to roof over the coil, and perforated to admit of the passage of the stem. The instrument must remain long on the part. It may be kept in place by a very thin caoutchouc band, split so as to be passed over the tube, and arranged so as to lie lightly around the limb with just enough pressure to keep it in place. Thus the pressure is kept the same, and in comparing the two members great care must be taken accurately to repeat this and other conditions. If the pressure be too great, it is sure to affect for a time the thin walls of the bulb, and then, as the instrument is lifted, the column instantly falls a little, this amount representing rise from excess of pressure. The coil-bulbs are less subject to this source of error.

The study of skin-temperatures has been fairly well made, but even yet may gain in accuracy and completeness. Moreover, there are some points as to normal temperatures rarely considered by neurologists in comparing the heat of symmetrical regions. Certain of these have come out clearly in the study made during the last year by me, and under my direction, by the staff of the infirmary, notably Dr. F. S. Pearce (late a resident), Drs. Taylor, Burr, and others.

Minute precautions are essential in dealing with minute differences, and in fact one may take it as a rule that the finer the instrument used the finer must be the human instrument using it. We still need a perfect surface-thermometer.

As the rise or fall in cases of local neuritis may be but slight, it is well to remember that normal differences as between right and left members are by no means uncommon. If, for illustration, in this healthy man at rest and supine, we apply the surface-thermometer and leave it at least ten minutes on the dorsum of the right foot, it notes 35.6° C., and on the left 35.2° C. Here is a fact of interest. The two feet are not always alike in temperature. At times the amount of difference is 1° C. Now let the man stand up, and with the thermometers in the same places they come to mark 35.4° C. and 34.9° C., respectively. This is one example taken at random. Meanwhile the mouth-temperature has remained unaltered. Certainly this is an interesting fact; it may have escaped notice.

Last spring, in a case of red neuralgia, we were measuring the temperatures of the feet in bed, and when hanging over the edge, or when dependent

from the hips, the man being on crutches. In the acute stage of this disease dependency of limb is apt to cause a rise of local temperature; but in the case in question, and perhaps in all, when the disorder has lasted long there is, under these circumstances, a fall of temperature and not a rise.

The fall in this case led me to study anew the natural thermal conditions, and after personally learning that the normal foot when dependent was likely to fall in temperature, I asked Drs. Taylor and Burr to test the matter. They both found the observation to be correct in themselves and in several of our nurses. I then asked Dr. Pearce, lately resident, to make a series of observations on the foot and hand. These have been done with care and skilfully varied. To save space I give these figures in tabular form.

In the following eleven experiments upon the *dorsum* of each foot (at the same time), the thermometers were read in twenty minutes, as the subject lay supine; then ten minutes later, the subject standing. The extremities were kept uncovered and away from draughts. The centigrade scale was used. The temperature of the room was 68° F.:

TABLE—EXPERIMENTS.

No.	Time.	Position of right leg.		Position of left leg.	
		Horizontal	Standing.	Horizontal.	Standing.
1	P. M.	35.6	35.4	35.5	34.9
2	P. M.	34.6	34.4	34.6	34.6
3	A. M.	33 6	32.8	33.6	32.4
4	A. M.	31.4	30 0	31.6	30.2
5[1]	P. M.	34.4	34.0	35 4	33.4
6	A. M.	34.8	33.2	34.0	33.2
7	Noon	35.0	35.0	35.8	35.6
8	P. M.	35.6	34.2	35 8	35.0
9	A M.	34.2	33.2	34.6	32.2
10	P. M.	33 6	31.8	34.0	32 4
11[1]	P. M.	33.6	31.0	34.2	30.4

The same conditions obtained in the following experiments upon the *soles* of the feet:

No.	Time.	Position of right leg.		Position of left leg.	
		Horizontal.	Hung over edge of couch.	Horizontal.	Hung over edge of couch.
12	A. M.	33.6	33.2	34.0	33.8
13	P M.	34.8	34.4		
14	P. M.	36.0	35.2		
15	A. M.	31.6	30.6	32 0	31.0
16	A. M.	30.8	30 4	29.0	29.0

The same conditions, the patient lying supine continuously:

No.	Time.	Palm of left hand.	
		Horizontal on couch.	Held up vertical.
25	P. M.	35.6	35.4
26	P. M.	34.6	34.2
27	P. M.	35.2	35.0
28	A. M.	35.6	35.4
29	A. M.	35.1	35.0
30	A. M. / P. M.	34.4	34.0

The conclusions that may be formulated as to surface-temperatures are as follows:

The temperature of the dorsum and sole of the feet is on an average from $\frac{2}{5}$° C. to 1° C. less when standing erect than when lying horizontally.

All things being equal, the morning surface-temperature is less than the evening surface-temperature on the dorsum or sole of the feet.

The mouth-temperature varies little as between lying down and standing; or if it changes there is a very slight rise.

The nearer the trunk the less do the surface-temperatures vary in different portions of the body.

The palms of the hands are the warmest parts of the extremities; their surface becomes less warm as the extremity is moved from a resting horizontal position to one of hanging down loosely, and finally to being held up in a vertical position.

The foregoing obtains whether the body lies supine or is held erect.

The two hands or the two feet vary somewhat in temperature in the same person under equality of conditions. At times the right member is warmer; at others it is the left.

[1] Experiments 5 and 11 were performed upon two old cases of erythromelalgia of the *left* leg in men twenty-one and thirty-four years of age respectively. All others were upon healthy persons.

ORIGINAL LECTURE.

BILATERAL CEREBRAL THROMBOSIS DUE TO SYPHILITIC ARTERITIS, WITH INCONTINENCE OF THE VESICAL AND ANAL SPHINCTERS.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY, TO THE ST. LUKE'S, AND TO THE DEACONESS HOME HOSPITALS.

I WISH to study carefully with you to-day the case of the man who is before us, as since his admission into the hospital it has presented several difficulties in regard to diagnosis. His history is as follows:

J. C., thirty-three years of age, a male laborer, of New York, but living in Colorado during the past three years, was admitted into this hospital July 11, 1893. His family history is unimportant, except for the occurrence of tuberculosis on his mother's side. His health was always good until four years ago, when he contracted a hard

[1] A clinical lecture delivered at the Arapahoe County Hospital.

chancre, but without secondary manifestations. After this his health seems to have been fairly good until about one month prior to the occurrence of the paralysis for which he was brought to the hospital. The symptoms premonitory of the paralysis consisted of headache and mental dulness for one month, and, for a few days immediately antedating the attack, dizziness. On the morning of July 11th (the day of his admission into the hospital), while he was sitting in a chair, his left side became paralyzed. He felt dizzy at the time, but he is quite sure that he did not lose consciousness. When he was brought to the hospital a few hours later, he seemed confused, but realized vaguely what was going on. His temperature was 98°, pulse 80, respirations 30, and there was incontinence of urine. He remained in about the same condition for four or five days, with normal temperature, total motor aphasia, and with complete paralysis on the left side, and nearly complete on the right side. At the end of this time he seemed brighter, and I had the following account of his condition recorded:

The mental condition seems to be good. The apparent mental dulness is partially caused by the motor aphasia, which is complete, as he is unable to utter the simplest monosyllable. The right leg is almost completely paralyzed. He is able to slightly flex and extend the right foot, but it is impossible for him to raise the foot from the bed. The flexors and extensors of the right knee and hip are extremely weak. Every muscle of the left leg is completely paralyzed and the knee-jerks are absent. The plantar reflexes on the right are slight, and for the great toe only, and on the left are absent. There is no ankle-clonus and the cremaster and abdominal reflexes are absent. The trunk muscles are weak, but not completely paralyzed, and the diaphragm acts well. The left arm and hand are entirely powerless; the right hand registers 48 on the dynamometer. The right-arm muscles are weak, but stronger than those of the leg. The deep reflexes are increased and most marked in the biceps muscle. The man has lost control of the sphincters of the bladder and anus. The muscles of the left side of the neck and face are paralyzed; those of the right side are weak. He is able to open and close the eyes and to frown. He can only protrude the tip of the tongue. Tactile sense, even over the external genitalia and around the anus, is well preserved. Although he seems a little slow in recognizing the contact of a substance, this delay may be only apparent on account of his inability to talk. The senses of temperature, pain, posture, and localization are normal, but the pressure-sense seems a little deficient on the right side. Smell, taste, and hearing seem nearly normal.

The right pupil is regular and normal in size, and reacts to light and in accommodation; vision is good and the fields are preserved; there is no disturbance of any of the external ocular muscles; vessels, disc, and fundus present a normal appearance. The condition of the left eye is about the same as that found in the right eye. On account of the loss of control of the vesical and anal sphincters, the tactile sense was repeatedly tested over the external genitalia and around the anal region, but it was always found normal.

A few days after his admission into the hospital his temperature, which had before been normal, rose to 101°, and remained above normal four or five days, one evening registering 102°.

The condition of the man from the time of his admission to the present has shown a gradual improvement, especially in the power of walking. His speech is very much improved, and the side that was totally paralyzed has gained considerable power, but the bladder has never entirely regained its function. He is able to control the sphincter ani, and sometimes for several days at a time he is able to control the bladder; at other times he is totally unable to prevent the bladder from involuntarily emptying itself.

I will examine him again to-day. He has fair power in the right leg, and uses it quite well. His gait is exceedingly awkward. The left leg is moved in a very ungainly manner, and in walking backward the left foot drags. He walks very much better forward than backward. The imperfect gait is due to muscular weakness and rigidity, and to lack of confidence in his ability to control his leg-muscles. You notice that his gait is different from that found in a person suffering from posterior spinal sclerosis. Whilst there is some incoördination in his gait, it is of a jerky character and is due largely to increased muscular irritability, and to contractures that have taken place in the flexor muscles of the legs, especially on the left side. He experiences little difficulty in standing with his feet close to each other, and on closing his eyes the difficulty is only slightly increased. Turning around makes him decidedly dizzy. The right knee-jerk is greatly increased, the left still more increased. On the left side several contractions of the rectus femoris muscle occur from once tapping the patellar tendon—a rectus-clonus. Ankle-clonus is absent on the right; present on the left. There is increased irritability, both of the anterior and posterior tibial groups of muscles on the left side, causing "paradoxical" contraction of the tibialis anticus when the left foot is forcibly dorsally flexed. The plantar reflexes on the right side are absent on the inner side of the foot and are slight on the outer; on the left they are nearly the same. The cremaster and lower abdominal reflexes are absent. The epigastric reflex is decided on both sides. The deep reflexes of the arms are slightly increased on the right side, and on the left are decidedly increased. The muscular power in the right leg is fairly good; in the left, rather weak. The dynamometer on the right registers, 130; on the left, 112, so that muscular power is pretty good, even in the left hand, with which he was unable to move the register of the dynamometer at all when he entered the hospital. The muscles of the face show but little weakness. The tongue is protruded fairly well now, although for several weeks he was unable to get it far beyond the teeth. The pupils react to light and in accommodation, and are equal in size. The sensory functions, including the special senses, are all preserved. His speech is perfect now, but his mental power is slow.

I wish to study this case with you somewhat in detail, as it presents many interesting features, both as to the seat and nature of the lesion. With the exception of headache and mental dulness, which antedated the paralysis for about a month, and dizziness, which immediately preceded the paralysis for only a few days, the man had always enjoyed good health, with the exception of syphilis four years ago, until the morning of July 11th, when,

while sitting in his chair, without apparent shock or loss of consciousness, his entire left side, including the face, became completely paralyzed. Just when the right-sided partial paralysis came on he is not aware, but it probably was almost simultaneous in its onset with that of the left side, as both sides were affected on his admission into the hospital, a few hours after his attention was attracted by the paralysis of the left side. He had incontinence of urine and feces, and was unable to speak, although he was conscious.

The question naturally arises: Where are the lesions situated that would give rise to these symptoms? Are they in the brain, the cord, or the peripheral nerves, or are all these involved? The paralysis of the left side of the face, and the paresis of the right side, as shown by his inability to protrude the tongue, and the affection of speech, demonstrate conclusively that the brain is involved.

What evidences have we of a cord-lesion? In all cases attended with incontinence of urine and feces due to central nervous lesion, unassociated with loss of consciousness or dementia, we naturally expect to find the lesion in the spinal cord.

We can exclude myelitis in this case, because the tactile, pain, temperature, muscular, localization, and posture senses are all normal. Tactile sense has repeatedly been tested over the external genitalia and around the anal region, and at each examination it has been found normal.

In poliomyelitis there would be no incontinence of urine if the case were uncomplicated; and what is of more significance, in excluding poliomyelitis, we have the presence of increased myotatic irritability in muscles that were, a few weeks ago, absolutely paralyzed, and are at present paretic. The absence of muscular wasting and the presence of electric irritability to the faradic current also aid in excluding poliomyelitis, as well as myelitis.

Multiple neuritis of alcoholic origin is occasionally attended with incontinence of urine, and perhaps with an increased knee-jerk, while, possibly, ankle-clonus may be present in some cases.

This man has been addicted to the use of alcohol, but he never drank steadily or heavily. One of the chief features of multiple neuritis is its symmetry. From the start this case has been asymmetrical. There has been absolute paralysis of the left side, including the face, arm, and leg, with incomplete paralysis of the right side. Other points against multiple neuritis even of alcoholic origin are: involvement of the trunk and face-muscles; the affection of speech, with inability to protrude the tongue; the absence of the psychical disturbances so common in alcoholic multiple neuritis; and the maintenance of muscular nutrition, which is never found in any case of multiple neuritis, no matter what its cause may be. The paralysis of multiple neuritis never comes on suddenly, as it has in the present instance, and this disease is usually attended with sensory perversion, all symptoms being most marked at the distal portion of the extremities.

After a careful review of all the symptoms presented by our patient, both now and throughout his illness, I feel justified in excluding multiple neuritis and disease of the spinal cord. Our patient must be suffering from multiple brain-lesions which are bilateral. Will bilateral brain-lesions account for all the symptoms presented by this patient?

One hemisphere of the brain controls the muscles of the opposite side of the body concerned in movements of a higher or more differentiated character, and, to a certain extent, the muscles on both sides of the body, which usually act in association with each other. The muscles that are most highly differentiated in their function from those of the opposite side of the body are those of the hand. The best types of bilaterally acting muscles are those of respiration, mastication, and those that move the eyes; therefore, a motor-paralyzing lesion of one side of the brain may cause absolute paralysis of the unilaterally-acting muscles of the opposite side of the body, and a slight weakness of the bilateral muscles of both sides. Such a lesion, unassociated with shock, unconsciousness, or mental disturbance of any kind, does not produce incontinence of urine or feces.

Sudden bilateral lesions of the brain occasionally occur, but they are usually unequal in their severity on the two sides of the brain. I see no reason for not attributing the incontinence of the sphincters of the bladder and anus to a bilateral brain-lesion.

Granting, then, that we have bilateral brain-lesions, it will be more convenient, in the present instance, to consider their location before trying to determine their nature. In all cases of sudden bilateral brain-lesions, our first thought is that the pons or medulla is implicated. The cranial nerves affected in our patient are the hypoglossal, making it impossible for him to protrude the tongue, and that portion of the facial, or seventh pair, distributed to the lower portion of the face. A sudden lesion in the nuclei of these nerves in the medulla must necessarily involve the nuclei of other cranial nerves, especially of the fifth, sixth, and eighth, adjacent to the facial nuclei, and of the ninth, tenth, and eleventh, which, are found close to the nuclei of the hypoglossal. Besides, such an extensive lesion must involve all the nuclei of the facial, thus affecting the upper as well as the lower portion of the face. Absolute paralysis of the same side of the face as of the body, with the upper portion of the face escaping, places the lesion above the middle of the pons. A lesion in the upper portion of the pons, causing paralysis of the opposite side of the body, will most invariably affect the fifth nerve on the side of the lesion, and when the lesion is bilateral in this portion of the pons, sudden and extensive enough to give rise to the extensive paralysis found in this case, it seems impossible for the fifth nerve to escape. A lesion in the crura would affect the third nerves, so that we may conclude that the lesions that have caused the symptoms presented by this man, are situated in the cerebral hemispheres. In the cerebral hemispheres, bilateral lesions, or a unilateral one, giving rise to motor paralysis on both sides, or on one side of the body, as the case may be, may occur in the internal capsule, in the centrum ovale, or in the cortex. Sudden occlusion of the large branches of the middle meningeal arteries on each side of the brain, sufficient to give rise to bilateral paralysis of the face, arm, and leg, would be attended by convulsions, profound unconsciousness, marked disturbance in temperature, and probably speedy death. It is rare, even in unilateral sudden cortical lesions, that they are so ex-

tensive as to involve the whole of one side of the body. Lesions of the centrum ovale, causing bilateral paralysis, are exceedingly rare. When they occur near the cortex they give rise to symptoms simulating those of cortical lesions, and when near the basilar ganglia, symptoms very much like those of lesions occurring from injury to these ganglia. It is not always possible to differentiate them; neither is it necessary for any practical purposes, except in a few rare instances. We must conclude, then, that the lesions in the patient whose case we are considering, are in the internal capsules, or in the white substance near them, but more probably in the former situation.

We shall next consider the probable nature of this man's lesions. For this purpose brain-lesions may be divided in regard to duration of onset into sudden, acute, and chronic. The chronic lesions that we need to consider to-day are morbid growths, aneurysm, and chronic abscess. The first two of these may be excluded by the history and the absence of optic-nerve inflammation and resulting atrophy. Chronic abscess is excluded from the history and the absence of a cause. The acute lesions are inflammatory in their nature, are several days, or longer, in reaching their height, and are attended by a rise in temperature. The absence of temperature-elevation, and the sudden onset of the paralyzing lesions in the patient before us, enable us to exclude inflammation. The onset of our patient's trouble was sudden, and the lesions reached their height in from a few minutes to a few hours. All such lesions, excluding traumatism, are vascular in their nature.

The diagnosis then rests between embolism, hemorrhage, and thrombosis. In young subjects the chances are in favor of embolism, as against hemorrhage, with the presence of endocardial disease or syphilis, except when the apoplectic symptoms are severe, especially with prolonged and profound coma. The less the primary disturbance of temperature, in the majority of cases, the less likely is the lesion of a hemorrhagic nature.

It seems to me that in all cases of sudden and extensive paralyzing lesions of the brain, not attended with unconsciousness and deepening coma, and with but slight disturbance of bodily temperature, a hemorrhagic lesion can be excluded. Slight hemorrhages may occur suddenly, with but little variation of temperature; so also may large, gradually-increasing hemorrhages take place without great affection of consciousness or bodily temperature at first. This man's paralysis was extensive from the first; therefore, from the symptoms that he presented at the time of admission into the hospital, we are justified in excluding hemorrhage. The age of the patient is more in favor of occlusion of a cerebral vessel than of rupture, but we must bear in mind that the youth of a patient is never very strong evidence against cerebral hemorrhage.

Gowers (*International Medical Magazine*, October, 1893) implies that a hemorrhagic brain-lesion in the substance of the brain in the young is always fatal. This may be so, but I think I have seen at least one exception.

Having excluded hemorrhage, we have left to consider embolism and thrombosis. We are not justified in diagnosticating embolism unless we can find a source for the embolus outside of the cerebral circulation. In the vast majority of cases of embolism the embolus is caused by an old or recent endocarditis, a vegetation washed from the endocardium or from the valves of the cardiac orifices.

In our patient there is no history of cardiac trouble, and on careful auscultation no murmur is found over the heart. We must remember that it is possible to have slight vegetations attached to the cardiac orifices, and yet no murmur be discoverable. This is most likely to be met with several months after the acute cardiac inflammation. But, even in such cases, there is commonly a history of heart-trouble. In certain profound blood-changes there may be a tendency to coagulation of the blood in distant portions of the body, and a clot thus formed may reach the brain and occlude one of the main arteries. The only blood-change in the patient before us is due to syphilis, but this has not been very marked, as his color seems fairly good. Having failed to find a source of embolism we are justified in excluding it. There are, however, two other reasons for dismissing embolism: the bilateral character of the lesions in the cerebral hemispheres, and the preservation of consciousness at the time of the occurrence of such extensive paralysis.

Excepting in cases of involvement of the basilar artery, the brain-symptoms from cerebral embolism are usually unilateral. When a vessel is occluded by an embolus, the occlusion takes place suddenly without premonitory symptoms, and if the vessel involved is a large one, consciousness is necessarily lost.

Having excluded the probability of hemorrhage or embolism in this case, let us see if the indications of thrombosis are sufficiently well-marked to justify such a diagnosis. Thrombosis is generally preceded by distinct premonitory symptoms. These were fairly well-marked in our patient, and consisted of headache and mental dulness for a month or more, and dizziness for a few days immediately preceding the onset of the paralysis. The occurrence of extensive paralysis without loss of consciousness is rather in favor of thrombosis than of embolism. The rise of temperature that occurred in this patient several days after his admission into the hospital, usually occurs in most cases of extensive occlusion of the cerebral arteries, due either to embolism or thrombosis.

Having arrived at the diagnosis of cerebral thrombosis, let us extend our inquiries further, to determine, if possible, the nature of this condition. A thrombus may form in one of two ways: first, by coagulation of blood in the vessel at the point at which the thrombus forms, from profound blood-changes, as in cases of marked anemia, great blood-deterioration from the syphilitic virus, and from vitiated blood-states from various other causes; and secondly, from changes in the walls of the vessels, also at the site at which thrombotic occlusion takes place. In considering the subject of embolism, we found no reason to suspect an undue tendency in this man's blood to coagulation; therefore, we must attribute the cause of the thrombosis to changes in the arterial walls.

There are only two forms of disease of the arterial vessels that favor occlusion of the arteries that go to the great ganglia at the base of the brain. These are atheroma and syphilis. Atheroma is essentially a senile change, and probably rarely, if ever, occurs in a person as young

as the man before us. We have, then, narrowed our diagnosis down to thrombotic occlusion of the arteries supplying the great ganglia at the base of the brain, and especially of those that carry blood to the anterior two-thirds of the posterior half of the internal capsules; and this condition we have seen is due to syphilitic disease in the walls of these vessels. The changes that take place in vessels affected with syphilis consist in gummatous deposits, inflammation, swelling, and in consequence a narrowing of the caliber of the vessel at the point affected. Often the inner surface of the vessel at the seat of narrowing is rough, and thus the formation of a clot at this point is still further favored. The most marked changes take place in the larger arteries at the base of the brain, but the lessening of the caliber of the vessels is most pronounced in the smaller arteries given off from the main branches. Sometimes the narrowing goes on gradually, almost to the point of occlusion of the caliber of the vessel, but finally complete occlusion by the formation of a clot takes place suddenly.

If you bear in mind the essential difference between embolism and thrombosis, it will not be difficult for you to account for the difference in the onset of the symptoms in the two processes of arterial occlusion. In embolism, up to the time of the lodgment of the plug in the vessel, the cerebral circulation had been perfectly normal, and no premonitory symptoms precede the arterial occlusion. In thrombosis, on the other hand, the arterial blood-supply to a portion of the brain has been gradually lessening for weeks or months, and premonitory symptoms, in proportion to the diminished blood-supply, are the result. In some cases these are slight, and unless diligent inquiry into the previous health is made, will be entirely ignored by the patient; whilst in other cases they are pronounced, and often consist of temporary numbness, paresis, or paralysis, with or without aphasia. Headache, mental dulness, and dizziness are often well-marked, as they were in our patient.

The result of thrombotic occlusion of a vessel is necrotic softening of the part supplied by the occluded vessel. When a large vessel is occluded, extensive softening will take place unless the circulation to that part of the brain is restored by collateral vessels. In the great ganglia at the base of the brain the nutrient arteries of these ganglia do not communicate with the arteries from the cortex, and in consequence, if the affected vessels are completely and permanently occluded, the softening will be complete, and the function of those areas of the directly-affected ganglia will be permanently lost. Fortunately, however, the vessels that are usually occluded in thrombosis at the base of the brain, in the neighborhood of the great ganglia, are often the smaller ones, so that the softening is not extensive. In all such cases the primary paralysis is more extensive than the permanent loss of power.

The prognosis in a case of thrombosis, other things being equal, is always worse when the trouble is bilateral than when it is unilateral. The immediate prognosis, or the chances of the patient escaping with his life, need not be considered here, as this man has passed this stage. What are the probabilities of his permanent recovery? It is unnecessary for me to go into all the elements that guide us in such an opinion, but let it suffice for the present for me to state that when ankle-clonus, exaggerated knee-jerk, and other evidences of increased myoatic irritability, with contractures of the flexor muscles of the extremities, are present, we have positive evidences of degeneration of the lateral columns of the cord, and neither a fair recovery nor marked improvement can take place.

The treatment of this case consists largely in making the man as comfortable as possible, encouraging him to go around on his crutches, but not allowing him to get fatigued; paying attention to the condition of the bladder, and trying to combat the affection of the arteries in order to prevent a recurrence of thrombosis.

In considering the treatment of syphilitic arteritis, it is necessary to bear in mind that the nodular deposits that take place chiefly in the outer and inner coats of the vessel are of slow and gradual growth, the caliber of the vessel being narrowed more and more, until finally the vessel is occluded by clotting of the blood in the diseased vessel. The deposition in the walls of the artery is a specific process, and to a greater or less extent is influenced by anti-syphilitic treatment, but the clot that finally occludes the vessel is a non-specific process, and is but little, if at all, influenced by mercury and potassium iodid. When thrombosis occurs in a syphilitic subject, the thrombus and the resulting softening take the same course in spite of active, specific treatment, that we find to occur in occlusion of a vessel from atheroma; therefore the outlook, so far as the brain-injury is concerned, is no better than in the case of a similar injury due to embolism, hemorrhage, or atheromatous thrombosis. Please remember that the occluded vessel or vessels in a case of thrombosis due to syphilis is not the only vessel diseased, but that in all probability many of the vessels at the base of the brain are similarly affected, but to a slighter degree. Your course of treatment then must not be an expectant plan, but you should endeavor to prevent other vessels from becoming occluded. The time when anti-syphilitic treatment is most effective, both in relieving the patient from present symptoms and in averting a hopeless paralysis, is when the premonitory symptoms first manifest themselves.

In what must this treatment consist? In the administration of mercury and potassium iodid only? No. I believe that we often fail in accomplishing the object of our treatment in syphilitic cases by sole reliance upon these two agents. We must remember that most persons who are suffering from the chronic effects of syphilis are in an impoverished state of health; therefore it is often necessary to administer iron, quinin, arsenic, together with the most nutritious food, in order to get the desired effects of mercury and potassium iodid. I have seen syphilitic subjects who had failed to improve after weeks of active treatment by these agents, begin to feel better, and lose one symptom after another on the same doses of potassium iodid and mercury that they had taken ineffectually for weeks before, after their general health had been improved by a tonic course of treatment. In syphilitic arteritis the large doses of potassium iodid that are so effectual in gummatous tumors of the brain are not only uncalled for, but they may be positively harmful by depressing the patient, impoverishing the blood, and thus favoring coagulation in the diseased arteries.

CLINICAL MEMORANDA.

A NOTE AS TO THE USE OF OXALIC ACID AS AN EMMENAGOGUE.

BY FRANK W. TALLEY, M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN GYNECOLOGY, PHILADELPHIA POLYCLINIC.

THE use of oxalic acid in the treatment of amenorrhea was first suggested by Dr. F. Paulet, and afterward introduced into American literature by Dr. A. W. Marsh in an article in the *Therapeutic Gazette*, March, 1891. It is recommended that the drug be administered in half-grain doses, repeated every four hours, and it is described as a safe and efficient emmenagogue.

During the past twelve months I have used it with very gratifying results in a series of cases of amenorrhea presenting themselves for treatment at the Polyclinic and at the Pennsylvania Hospital. While I value oxalic acid as an emmenagogue, I cannot entirely subscribe to the conclusions drawn by Dr. Bloom in his article in THE MEDICAL NEWS of October 14, 1893. While an efficient emmenagogue and a capable abortifacient, oxalic acid is not to be regarded as a perfectly safe drug. I have in the last month met with a case in which toxic symptoms followed the ingestion of three doses of half a grain each repeated at about four-hour intervals. The patient was an anemic girl, twenty-two years of age, who gave a history of scanty menstruation and a complete cessation of her periods for three months. The uterus was not enlarged nor were there any of the signs of pregnancy. She was placed upon oxalic acid in half-grain doses, which she was directed to take after meals, largely diluted with water. After the third dose she was seized with vomiting, pain in the epigastrium, and became completely prostrated. The pulse was weak and rapid, and the extremities cold. She was placed in bed, external heat was applied, and the symptoms of collapse were soon overcome. She then complained of cramp-like pain in the hypogastrium and back. These symptoms were followed by an eruption upon the arms, trunk, and legs, resembling that of hives, which was still present seven days later and was attended with considerable itching. The symptoms gradually diminished in severity, the gastric symptoms being the most pronounced.

The action of oxalic acid seems to be directly as a stimulant to the uterine mucous membrane. It is, therefore, applicable to the treatment of amenorrhea of the anemic as well as of the plethoric type. Upon the pregnant uterus oxalic acid is capable of producing powerful uterine contractions which terminate in the expulsion of the product of conception. This was observed in two cases of early physiologic amenorrhea to which oxalic acid had been administered, the diagnosis of pregnancy not having been made.

Considering the fact, therefore, that oxalic acid, even when administered in fractional doses, is capable of producing toxic symptoms, and bearing in mind its powerful abortifacient properties, we should be guarded in recommending it as a safe remedy. I consider it a valuable drug in the treatment of amenorrhea, but one that should be given guardedly, carefully watched, and only prescribed when the diagnosis of pregnancy has been excluded.

FRACTURE OF THE BASE OF THE SKULL; RECOVERY.

BY GEORGE W. CRILE, A.M., M.D.,
PROFESSOR OF PHYSIOLOGY AND LECTURER ON MINOR SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF WOOSTER, CLEVELAND, OHIO.

ON August 15, 1893, the subject of this report fell from a scaffold fifty feet high, striking on the back of his head. When found he was unconscious and remained so for five days. Blood and serum escaped from both ears for two weeks after the accident. There was intense pain in the left eye, and the lid could not be closed. The patient was taken to the Huron Street Hospital, where he remained for about two weeks. I first saw him in my service at the City Hospital two weeks after the injury. I found that the left eye could not be closed, that there was diplopia, some headache, and complete paralysis of the abducens and facial nerves, also paralysis of the sensory division of the trigeminus. Dr. Upson, who kindly examined the eye, found the fundus normal. The pupil was in a constant state of mydriasis. Hearing was somewhat impaired on the left side. The patient was thirty-seven years old, of good individual and family history, and there was no evidence of specific disease to be found. The diagnosis of fracture of the base of the skull rests on the history of the violent injury to the head, followed by the discharge of blood and serum from the ears for two weeks, and paralysis of certain cranial nerves. The treatment consisted in full dose of potassium iodid. After several weeks the paralysis disappeared, all the lost functions were restored, and the patient left the hospital apparently well. From the symptoms and the history I have made the diagnosis of pressure from blood-clot at the base of the brain on the nerves paralyzed. There is a point at which a clot might press on these branches and yet be comparatively small.

I do not insist on the causal relation of the treatment to the recovery.

NEW INSTRUMENT.

A SPIRAL OSTEOTOME FOR OPENING THE SKULL IN BRAIN-SURGERY.

BY M. H. CRYER, M.D., D.D.S.,
OF PHILADELPHIA.

DURING the past year the surgical engine, with its appliances, has been so greatly improved that its general use for bone-operations can no longer be questioned. The hand-piece has been enlarged, enabling the various cutting instruments to be more firmly placed, while room has been obtained for the attachment of guards of suitable kinds. The instrument can also be easily and quickly taken apart, cleaned, and made thoroughly aseptic. A velocity of from 10,000 to 12,000 revolutions a minute can be obtained, with great steadiness and regularity of speed.

One of the new appliances—a circular saw, having an adjustable guard for opening the brain-case—was used successfully lately in an operation performed at the Orthopedic Hospital by Professor W. W. Keen, for the removal of the Gasserian ganglion. The advantage gained by the use of this saw was the rapidity with which it cut, yet perfection seemed lacking, in that the mallet

and chisel had to be called into requisition for supplementary work. This case, as well as a series of carefully conducted experiments upon the cadaver, shows, however, that all danger of wounding the dura is not absolutely eliminated even by the use of the guard which is attached to the mandrel of the saw to prevent the penetration of its cutting-edge beyond a previously determined depth. The danger exists in the fact that brain-cases vary in thickness, and even the individual skull is thicker in some parts than others, thus making it impossible to accurately fix the guard.

A number of experiments have been carried out by the writer with the hope of overcoming the danger of wounding the membranes either with the saw or in the final cutting of the bone with the chisel and mallet, the latter adding materially to the shock, and not being free from the possibility of puncturing the brain.

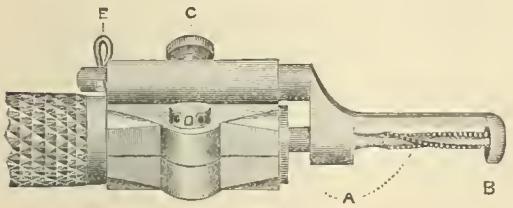
After many trials of variously constructed burrs, the following arrangement was hit upon, which seems to completely fulfil the requirements. The cutting portion of this "spiral osteotome" (Fig. 1) is one-half inch in length, one-eighth inch in diameter, and tapers slightly from base to point. By three spiral grooves, each

FIG. 1.[1]

Twice the size of cutting-tool.

having a turn of one hundred and twenty degrees through the half-inch from base to point of the cutting end, it is divided into three blades, giving it an appearance somewhat similar to a twist-drill. The effectiveness of these blades is enormously increased by a spiral

FIG. 2.[1]



Full size of instrument.

screw, forty-four threads to the inch, cut around the blades of the instrument. This device necessarily adds twenty-two teeth to the edge of each cutting blade. The individual teeth are so arranged with reference to one another that the cut made by one tooth is overlapped by that of the one next following, while the spiral arrangement of these teeth, in connection with the three spiral grooves, makes the burr perfectly self-cleaning, the débris being rapidly thrown out backward by the revolution of the instrument. The point of the burr when in use is guarded by a rounded, button-like attachment, connected with the nose of the hand-piece by means of a shank and collar, as shown in Fig. 2 at A. The free end of the burr is dowelled into a seat in the guard A, in which it revolves, which steadies the whole arrangement when in use, gives an added rigidity to the burr-shank, and holds the burr and guard in permanent relationship to each other.

It will be seen that the principle involved in the instrument described is simply that of a saw arranged to cut in a line with the axis of the shaft of the burr, and not at right angles to it, as in the circular saw. Such an arrangement allows of cutting in any direction and upon curved lines. This feature is especially valuable in resections of the brain-case, inasmuch as fenestra of any desired shape or size may be speedily made.

In operating for the removal of a portion of the brain-case with the spiral burr, after division of the soft tissues by the scalpel, a small opening is first made with a trephine mounted in the engine handpiece; this trephine has a diameter of five-sixteenths of an inch, and is passed completely through both tables of the skull, and the button of bone removed. There is no danger of injuring the dura with the trephine if it be carefully used. The opening thus made affords a means of entrance for the cutting burr, which, with its protecting guard, is next inserted in the opening, and the section made along the lines previously determined, by running the engine at high speed and forcing the bit laterally in the direction desired.

The button-like guard at the point of the burr absolutely prevents injury to the dura, which is pressed or dissected away by it from its attachment in the line of the cut as the instrument progresses.

The detailed description here given is of an instrument that I have called the spiral osteotome, which was designed for the special operation under consideration. Other instruments, simple modifications of this, would, of course, be needed, and could be easily made for other operations upon bone. A longer instrument, with or without a guard, could be used for resection of the long bones, of the femur, for example, in any part of its length, even at the head, while in the acetabulum. To remove diseased or nodulated bones of the nasal cavities, instruments of the same size, but with longer shaft and without the guard, could be made. Drills upon this fundamental type can also be made by lengthening and tapering the three spiral blades to a point, and large burrs of various shapes, by increasing the number of spiral-toothed blades in definite relation to the size of the cutting instrument required.

MEDICAL PROGRESS.

Fatal Intoxication with Hydrogen Arsenid.—MARTIN (*Medical Chronicle*, vol. xix, No. 2, p. 108) has reported the case of a foreman in a chemic works, thirty-one years old, who was made ill and vomited after having engaged for a half-hour or more in treating spelter or zinc bars with commercial hydrochloric acid, without adopting the usual precautions for carrying off the vapors generated. He attempted to go into the open air for a walk, but found himself unable to get about. He complained of pain in the head and abdomen and loins. The urine passed was dark, and sleep was disturbed by repeated vomiting. The eyes were suffused; the conjunctivæ and skin were stained deep-yellow; the respiration was normal; the pulse was rapid and irregular; the temperature was normal; the bowels had

not moved; but little dark opaque urine, resembling blood, had been passed; hiccough was at times severe and troublesome. The administration of a Seidlitz powder was followed by two dark slate-colored evacuations from the bowels. The symptoms continued for five days, gradually moderating, when on attempting to get out of bed the patient was seized with a convulsion, in which he died. A post-mortem examination could not be secured. Examination of the urine disclosed the presence of blood-corpuscles and their disintegrated remains; the spectroscopic reaction of hemoglobin and the chemic reaction of arsenic were obtained. The blood examined during life contained degenerated red corpuscles that failed to form rouleaux. A large proportion of arsenic was found in the hydrochloric acid that had been used, and only a trace in the spelter. It is noted that the symptoms present bore a close similarity to those of acute atrophy of the liver.

Arsenical Peripheral Neuritis.—At a recent meeting of the Clinical Society of Manchester, RAILTON (*British Medical Journal*, No. 1714, p. 996) presented a girl, ten years old, who had been under treatment for chorea of three months' standing. Fowler's solution of potassium arsenite was prescribed, and in three weeks the chorea was cured. Five drops were given three times a day for three days; ten drops three times a day for three days; fifteen drops three times a day for fifteen days, a total of thirteen and a half drams, equivalent to six and three-quarters grains of arsenious acid. During the continuance of the treatment the girl showed symptoms of gastric derangement, and two days after the withdrawal of the medication she was noticed to be desquamating freely. Ten days later she could not walk alone, and complained of pains in the arms and legs, the latter being particularly sensitive to pressure. When she put her feet down she felt "pins and needles." She was unable to button her clothes. The knee-jerks, which were active before treatment was instituted, were lost. The feet could not be flexed upon the ankles and if, supported, the girl attempted to walk, the soles of her feet were entirely visible from behind. The affected muscles in the legs displayed reactions of degeneration. There was distinct impairment of coördination. The urine was slightly albuminous. Of nine other cases treated similarly, seven had vomiting, one diarrhea, three herpes zoster, two erythema, and one peripheral neuritis, though not in so intense a degree as the case detailed.

Glycosuria During Infancy.—GROSZ (*Pest. med.-chir. Pr.*, 1892, No. 37; *Centralbl. f. klin. Med.*, No. 44, p. 951) has studied the urine of 50 nurslings between the age of one day and four weeks. This number included 24 healthy children, 1 premature child, 1 case of hydrocephalus, 14 cases of acute and chronic gastro-enteritis, and 10 cases of other forms of dyspepsia. Among the 50 cases the urine of 10 caused a reduction of Trommer's test with cupric sulfate. In 2 cases the results were confirmed by observations made with the polarimeter. These 10 cases included 7 of aggravated gastro-enteritis which terminated fatally, and 3 of mild dyspepsia. It is assumed that the glycosuria was of alimentary origin. Subsequent investigation disclosed the fact that the administration to infants of quantities of milk-sugar exceeding a given amount was followed by a reaction of the urine to Trommer's test. Healthy children bore a larger amount without change in the urine than children suffering from gastro-intestinal derangement. To this fact, and perhaps also to the influence exerted by the bacteria of the intestinal tract upon milk-sugar, it is thought the glycosuria observed in infants with deranged digestion may be due.

Lead-poisoning from Tea.—FREEMAN (*Lancet*, No. 3663, p. 1185) reports five cases of undoubted lead-poisoning and some half a dozen cases in which there were obscure abdominal pains and constipation without the presence of a lead-line, in three of which the source of intoxication was carefully looked for but could not be detected. In one case the tea used was examined, but with a negative result. Nine other cases presenting a well-marked blue line, as well as several others in which there were abdominal pains and constipation, coming under observation at a later period, the tea was again examined, and this time with positive results. Lead was found in varying amount, both in the loose tea supplied to some of the patients and in quarter-pound packets wrapped in lead-paper. In all of the cases abdominal symptoms were present, together with marked pallor, severe facial neuralgia in one, pains in the limbs in another, and gout in a third. In two or three cases there was vomiting, and in one or two diarrhea. In one case a relapse took place.

THERAPEUTIC NOTES.

Di-iodoform is the name given by MAQUENNE and TAINE (*La Semaine Médicale*, 1893, No. 66, p. 524), to a new antiseptic which is proposed as a substitute for iodoform. Chemically it is ethylene periodate, and consists of carbon, 4.62 parts, and iodin, 95.38 parts. It is insoluble in water, slightly soluble in alcohol and ether, but dissolves readily in chloroform, carbon disulphid, benzine, and hot toluene. It crystallizes in beautiful needles, quite distinct from the hexagonal plates of iodoform. If kept in the dark it remains practically odorless. The compound is an exceedingly stable one. It is prepared by treating acetylene periodate with iodin in excess.

In the Treatment of Pulmonary Tuberculosis, CARASSO (*Centralbl. f. Bakteriol. u. Parasitenk.*, B. xiv, No. 22, p. 719) recommends the continuous inhalation of mentha piperita, in conjunction with the internal administration of an alcoholic solution of creosote, with glycerin and chloroform, and containing 1 per cent. of mentha piperita. The most gratifying results were obtained in thirty-nine cases of pulmonary tuberculosis at various stages of the disease, the tubercle-bacilli disappearing from the sputum, the physical signs receding, and improvement in the general nutrition taking place.

THE PRIMARY ANEMIAS.

THE classification of the various forms of anemia on a scientific pathologic basis has of late been repeatedly attempted, though we must confess with little success. The great and substantial additions to hematologic knowledge encourage the hope that a satisfactory classification may soon be attained, but thus far they have only served to indicate the fallacies in existing schemes. The older text-books very carefully pointed out the features of what was known as simple anemia, and indicated the existence of a disease the essence of which was supposed to be a depraved condition of the blood. The first step in the direction of more complete knowledge was the removal of anemia from the list of independent diseases, and it is doubtful whether this term is now used by any authority of note, excepting in the clinical sense, as indicating a group of symptoms occurring secondarily in a variety of affections. The old anemia has thus given place to "secondary" or "symptomatic anemia," and a diagnosis is no longer complete until the underlying cause of the anemia and of the other symptoms is discovered. So far as the existence of an independent disease of the blood itself is concerned, a little reflection will show that such cannot be possible. The blood is a tissue in a limited sense only; for, though it contains living cells and a fluid intercellular material, the one great attribute of independent tissues, that of reproduction, is entirely wanting. It is therefore altogether dependent on other tissues, the blood-making structures, for its continued maintenance, and in turn a disease of the blood itself could exist only so long as the particular cells of the blood at the time of incidence of the disease in question existed, a period of time which has been variously estimated at from two to three weeks. It is evident, therefore, that a blood-disease must depend upon some pathologic condition outside the blood itself, which affects unfavorably the production or the destruction of the blood, decreasing the former or increasing the latter, or causing both at the same time.

In a certain sense, therefore, all forms of anemia are secondary or symptomatic, the actual disease being other than that of the blood itself; but the intimate relation of certain organs to blood-formation led to the separation from the ordinary secondary anemias of a group of anemias supposed to be due to disorder of the blood-making organs, and to the designation of such as primary or essential anemias. Very soon, however, it became evident from observation, as it had from a theoretic standpoint been obvious, that anemia might result from increased destruction of blood as well as from deficient production; and the classification of anemias as primary (in the sense of decreased production) and secondary lost some of its first attractiveness. The attempt, then, to separate the cytogenous, in which blood-making is at fault, from the hemolytic anemias, in which destruction is excessive, quickly suggested itself, but has thus far failed from the lack of definite knowledge; and it may be doubted whether such a division will ever be shown to be a natural one. Arbitrary distinctions and classifications will not stand the test of time in medicine any more than in other branches of science, and there is grave question whether or not a separation of cytogenic from cytolytic anemias would prove an advantage, even were we able to make the distinction.

The attempts, however, to determine this question have led to investigations into the ultimate manner of occurrence of anemia, which will surely bear rich fruit hereafter. Among these studies none deserves more careful attention than the recent work of DR. WILLIAM HUNTER on the physiology and pathology of blood-destruction (*British Medical Journal*, November 26 and December 3, 1892; London

Lancet, November 26, December 10 and 17, 1892). The well-known papers of the same author, published a few years ago, place him among the prominent advocates of the hemolytic nature of some of the forms of anemia, and his recent careful experimental work goes far to establish definitely some of his previous claims.

From the pathologic standpoint, progressive pernicious anemia has been looked upon as the most important form of anemia, as it is the most fatal; and the investigations into the physiologic pathology of this disease are therefore of prime importance. The theory of Prof. Pepper that alterations of the bone-marrow are the essential pathologic basis was an attractive one, and seemed to possess a considerable deal of evidence in its favor; but, as Henry pointed out, the medullary lesion is by no means a constant one, and this theory must therefore be abandoned. A next step in the study of the disease was the discovery of ankylostomum and bothriocephalus as the etiologic factors in certain cases; and a still more important advance, in certain respects, is the knowledge that the mucous membrane of the stomach and intestines is atrophic in other cases. Attention is thus directed at once to the gastro-intestinal tract for an explanation of this disease, and one naturally recalls the view of the late Sir Andrew Clark that chlorosis is primarily due to constipation and consequent copremia. Theoretically, one can readily conceive that the blood, exposed over a large surface in the gastro-intestinal tract, might, by the action of noxious agents within the digestive system, undergo destruction or hemolysis to an extent which no amount of normal hemogenesis could counterbalance, and there is certain proof of this. In the first place, there is evidence in this disease, in the abnormal pigmentation of the liver, in the high color of the urine, and in the microscopic features of the blood itself, that a high degree of hemolysis does occur. These facts draw attention at once to the liver and spleen as probable seats of the destructive process, with the result that abnormal pigmentation is found in the former, and no definite abnormality at all in the latter; but the existence of gastric atrophy or of intestinal parasites at the same time suggests a more intimate relation of the digestive tract with hemolysis than has hitherto seemed probable, despite the theoretic deductions of Sir Andrew Clark. It is in this connection particularly that we find the recent studies of Hunter of intense interest. He was able to show that the administration of toluylendiamin caused rapid destruction of the blood-corpuscles, first affecting those of the splenic vein, and when given in small enough doses affecting these alone. When, however, the spleen was extirpated there was evidence of hemolysis in the blood of the gastro-intestinal veins before that of the liver or other situations. It is needless to quote at length the experimental evidence brought forward, but we are inclined to give ready acquiescence to the conclusions of Hunter that the most active hemolysis takes place in the spleen, that the lymphatic and epithelial structures of the gastro-intestinal tract stand next, and in the absence of the spleen very largely assume this function, while in any case the liver is active only, or largely, in transforming or eliminating the hemoglobin and other substances set free in the spleen or digestive tract.

We are thus furnished with experimental evidence sufficient to indicate, if not to establish definitely, that the gastro-intestinal atrophy found in pernicious anemia plays a more important rôle than that of a result of the anemia, and that the intestinal parasites named affect the condition of the blood by increasing hemolysis, either through direct action on the normal digestive processes or by specially elaborated poisons, rather than by mere abstraction of blood, as has been held.

We may upon the same lines apply these thoughts to chlorosis, though in this disease the evidences pointing to active destruction of blood have been less accurately determined. Certain it is, however, that chlorosis and pernicious anemia are closely related in their ultimate pathologic nature, as cases of the former have been known to be transformed into the latter, and, perhaps, also the reverse. We are, therefore, far from ready to give accord to the classifications proposed, in which pernicious anemia is placed at one end of the scale, as being the most decidedly hemolytic form of anemia, while chlorosis is far removed and set down as a typically cytogenous form.

The clinical deductions of Sir Andrew Clark, while they have not as yet received the confirmation of experimental investigation, such as Hunter has furnished in the case of pernicious anemia, are not without an amount of indirect proof sufficient to establish their soundness, even though we are not prepared to go to the full length of their author in designating the intestinal disturbance as the essential cause of this disease. The anemic state induced by chronic dyspepsia, gastro-intestinal catarrhs, and constipation,

cannot certainly be laid to faulty cytogenesis as reasonably as to increased hemolysis, if the recent investigations of HUNTER be accurate, for, while there is an immediate and appreciable disturbance of the gastro-intestinal functions to explain the occurrence of hemolysis, the formation of blood could be interfered with only by the general reduction of systemic tone, a possibility far more remote than that which we assume to be present. We take it, therefore, that in both chlorosis and pernicious anemia, as well as in the various forms of anemia secondary to other diseases, hemolysis is an important factor; but at the same time we are not unmindful of the existence of deficient hemogenesis in the same diseases.

As HENRY has pointed out, it would be irrational to regard the large flabby megalocytes of extreme anemia as products of hemolytic change—and we may add also the nucleated red corpuscles in the same diseases. Both of these are doubtless results of disturbed cytogenesis; but we regard them in an indirect way as further proof of the great hemolysis going on at the same time. It is well known that a large hemorrhage speedily leads to the appearance in the blood of large, small, and nucleated red corpuscles, whose presence certainly is not to be ascribed to blood-destruction, but rather to efforts at rapid cytogenesis, resulting in the discharge of cells in an immature condition. The same conditions are doubtless present when rapid destruction of blood in the spleen or the gastro-intestinal tract takes place, and we are therefore inclined to regard both chlorosis and pernicious anemia as hemolytic and cytogenous at the same time.

The theory of VIRCHOW, that chlorosis is essentially a disease of blood-formation, due to congenital hypoplasia of the vascular system and of the blood-making tissues which have the same embryologic origin, need not therefore be abandoned, for it is quite likely that the hemogenetic function is sufficient in normal individuals to meet extraordinary demands, as well as the ordinary requirements of physiologic life, while in certain individuals this reserve force is wanting. It is, therefore, reasonable to suppose that persons of the type described by VIRCHOW would become chlorotic when active hemolysis occurred in the way we have indicated, or in other ways.

A similar thought might also be applied to pernicious anemia, as the bothriocephalus latus induces this condition in but a minority of the individuals infected, though the conditions are alike in all. In the case of ankylostomum, on the other hand, the pernicious type of anemia is much more frequent, as we might expect from the knowledge that this parasite occasions a considerable daily loss of blood in the intestinal canal, as well as serious disease of the mucosa, so that the number of individuals possessed of sufficient blood-making power would naturally be considerably smaller.

If, then, the view we have expressed—that chlorosis and pernicious anemia are due to active hemolysis, and at the same time deficient hemogenesis—be correct, it is apparent that the attempt to separate the anemias into groups, owning one or the other as their fundamental cause, must fail; and it is equally evident that the older classification of primary and secondary anemias is quite as fallacious. Our present knowledge of anemia strongly indicates that all forms are to be regarded as secondary conditions, and that the ultimate distinctions will be directed rather to the affections with which they are associated than to the type of anemia itself. In the case of the lymphadenopathies, attended with anemia, and which clinically manifest themselves as leukemia, Hodgkin's disease, or purpura hemorrhagica, this necessity for more accurate pathologic knowledge is still more evident. There is certainly a wide difference in the nature of those acute cases of leukemia, which, beginning abruptly in a manner entirely like that seen in infectious diseases, run a rapid course and terminate fatally in a few days, from the classic chronic leukemia in which infection is so remotely suggested, or from the cases which begin apparently as localized sarcoma, and subsequently invade widespread portions of the body. So, too, in the case of pseudo-leukemia, the determination of tuberculous lymphadenitis in some cases, and rapid infective disease in others, permits little doubt but that quite different diseases are manifested by the same or a similar clinical course.

It must be admitted that there is a great advantage for the present in retaining the old terms, and, indeed, this is necessary as we have arrived at no satisfactory classification of a different sort; but it is necessary at the same time to remember that when we speak of leukemia, or pseudo-leukemia, or pernicious anemia, or possibly also chlorosis, we use these terms in a clinical sense only, as we now speak of anemia as a condition and not a disease.

EDITORIAL COMMENTS.

Medicinal Preparations as Intoxicants.—The question is an interesting one as to where the line of law is drawn between a certain class of alleged medicinal preparations and intoxicants, so that a person may know when the one is put on the market whether or not it is in violation of the statutes with regard to the other. A recent Alabama case presented this point for adjudication. Here there was a "ginseng cordial" sold, which it was claimed was a medicine containing only sufficient alcohol to prevent fermentation. But the only evidence adduced in support of this theory was that "the mixture consisted of thirty parts of water, eight parts of alcohol, two parts of simple syrup, and ginseng and other roots and herbs possessing medicinal properties." On the other hand, an expert testified that he had analyzed the cordial, and found that the ginseng and other herbs it contained had no medicinal properties whatever; and the evidence further went to show that the cordial was not sold to, or used by, sick persons, but was sold to persons having no occasion for a medicine, and drunk by them, to intoxication, as a beverage. The decision of the Supreme Court of the State in the case, which is really what is of most interest in it, is to the effect that the word "intoxication," in its ordinary significance, means an abnormal mental or physical condition due to the influence of alcoholic liquors, a visible excitation of the passions, an impairment of the judgment, or a derangement or impairment of physical functions or energies. This, it says, implies a condition which would not result from the reasonable, ordinary, and moderate use of the most intoxicating liquors. Intoxication by means even of those liquors which the law itself recognizes as *per se* intoxicating, in general acceptance, is produced by their unreasonable, inordinate, immoderate, or excessive use, and to say that no liquor is intoxicating unless its moderate and reasonable use will produce inebriety is to declare that no liquor whatever is intoxicating. This cannot be, and is not, the test. The true criterion is that declared by Justice Brewer in the Kansas Liquor Cases. It is thus stated: "If the compound or preparation be such that the distinctive character and effect of intoxicating liquor are gone—that its use as an intoxicating beverage is practically impossible by reason of the other ingredients—it is not within the statute. . . . On the other hand, if the intoxicating liquor remain as a distinctive force in the compound, and such compound is reasonably liable to be used as an intoxicating beverage, it is within the statute, and this, though it contain many other ingredients, and ingredients of an independent and beneficial force in counteracting disease or strengthening the system."

Given that the particular compound will intoxicate, the question is not what quantity of it is necessary to produce intoxication, but whether the necessary quantity, however great or small, may reasonably be drunk. It is of no consequence that it may require from two to eight bottles of "ginseng cordial" to produce intoxication, if that quantity may be taken without other deleterious consequences than such as are incident to intoxication. If the quantity requisite to a state of intoxication may be safely used, it is a compound "reasonably liable to be used as an intoxicating beverage," within the statute. Upon no principle or reason can the quantity required to produce intoxication alone have any bearing on the matter, so long as the compound is agreeable to the taste and the necessary quantity may be safely taken.

Selfish Charity.—It is a sad fact that indiscriminate charity to the seeming unfortunate results usually in multiplication of the very misery the charity is supposed to lessen. Such charity hires criminals to make suffering. The "supply" will always rise equal to the "demand." In Croatia an organization of human fiends has been found whose business it was to mutilate children in order to exhibit them to excite compassion. The "deformity-market" was kept well supplied. The bones of children were broken, their heads crushed, their bodies twisted, bent, doubled, distorted in atrocious hideousness. In China the art has been carried to incredible extremes. "Wild men" have been created by transplantation of the skin of wild animals over the entire body, and teratologic monstrosities produced by causing inflammatory adhesions of the skin, *e. g.*, between a man and a boy. The production of Kaspar Hauser-like beings by confinement for years in the dark or in earthen jars was also practised. Such things are unknown in civilized countries, but when one gives money to "relieve distress" the probability is that he thereby encourages and doubles the wretchedness he would relieve. The only way to obviate this is by means of the charity organization societies. Indiscriminate medical charity is but a corollary of the same truth. There is poison in unearned bread, and drugs lose their physiologic reactions upon encouraged paupers.

Effect of Intoxication on Testamentary Capacity.—A man may habitually indulge in intoxicants, and yet possess testamentary capacity, the Prerogative Court of New Jersey holds, in the case of Fluck *vs.* Rea, if at the very time of the execution of the will he is able, and does, clearly comprehend the nature and effect of the business in which he is engaged. The rule in such cases is there quoted from Chief Justice Denio, of New York, and is in this language: "It is not the law that a dissipated man cannot make a contract or execute a will, nor that one who is in the habit of excessive indulgence in strong drink must be wholly free from its influence when performing such acts. If fixed mental disease has supervened upon intemperate habits, the man is incompetent, and irresponsible for his acts. If he is so excited by present intoxication as not to be master of himself, his legal acts are void, though he may be responsible for his crimes."

Moral Depravity does not Legally Establish Mental Insanity.—No reliable estimate of one's mental condition can be predicated upon isolated and independent acts. It is the entire line of conduct, each act examined with reference to that which preceded and that which followed it, that indicates whether the man is controlled by the dictates of sense and reason, or by the illusions of a disordered mind or imagination. And mere eccentricities of habits or perversion of feelings and conduct, forming what is termed "moral insanity," do not, it is held, constitute legal incapacity. The law recognizes the fact that proof of moral depravity does not necessarily establish a lack of intellectual ability.

SELECTIONS.

THE GREAT MEDICAL ERROR OF THE DAY.

In the treatment of the diseases of women at the present time there seems to me to be a tendency to lay too much stress upon lesions of the reproductive organs. Too little heed is, therefore, given to the nerve-element of woman's diseases, and, as a natural sequence, the surgical feelers and antennæ of the medical profession, always too keenly sensitive, vibrate vehemently at the approach of an ailing woman. This trend of the profession, to appeal to the knife as the great panacea for woman's diseases, is seen everywhere. It prevails alike in city, town, village, and hamlet. It asserts itself in every medical discussion, and stands out in bold relief upon the pages of every medical journal. It has caused many needless sexual mutilations and unnecessary operations, and it is, in my opinion, the great medical error of the day.

It comes, not so much from the glamor surrounding surgery, nor from the greed of gold, but from errors of judgment and from mistaken diagnosis. These arise from the fact that woman, through her sensitive and emotional organization, is a bundle of contradictions. More pitiful than man, and more long-suffering, her anger is more cruel and her jealousy more relentless. Feebler than man, an appeal to her affection will make her surpass him in sheer muscular endurance. Who can nurse her kin so untiringly, and with so little rest, as even a frail woman can? What father can equal a mother in fondling and soothing a sick and fretful child through the weary night-watches? What man can undergo the sheer fatigue, the strain and stress that a woman will for those she loves? Even in her pleasures, her physical amusements, she will, through keen enjoyment, often outtire the strongest man. In one word she is a creature of impulse and of emotion. But all nerve-strains, whether arising from the emotions, from the affections, or from the passions, have their reactions, and very strange and very misleading reflexes come from the loss of brain-control over insubordinate lower nerve-centers. For what is hysteria but nerve-misrule and the panic of the brain at incompetent control. The secret and sanctity of woman's inner life lies in her affections, and what disturbs them disturbs the nerves, and through them their environment of flesh and blood. These unruly nerve-lights flashing and fading at their own will, and without control, in the different organs of the body, the most careless observer may sometimes plainly see, for the clue is then as secure as the steps of a geometrical problem. But then again the symptoms are more frequently obscure. Often they are as misleading as the lapwing's flight. To construe such symptoms, to unfold their sense, and to paraphrase them, so as to gain a true conception of their character, often demands a deep acquaintance with human life and a keen insight into the most secret springs of its action.

Again, what is very perplexing, uterine symptoms are by no means always present in cases of uterine disease; and, what is still more bewildering, when so-called uterine symptoms are then present, they need not necessarily come from the uterine disease. The nerves are mighty mimes, the greatest of mimics, and they cheat us by their realistic personations of organic disease, and especially by their life-like imitations of uterine disease. Hence it is that even seemingly urgent uterine symptoms may be merely nerve-counterfeits of uterine disease. In fact, the time has come when we must give up the belief, which with many amounts to a creed, that woman is woman because she has a womb, and that the womb is at the bottom of nearly every female ailment.

Nerve-strain, or nerve-exhaustion, comes largely from the frets, the griefs, the jealousies, the worries, the bustles, the carks and cares of life. Yet, strangely enough, the most common symptoms of this form of nerve disorder in women are the very ones which lay tradition and dogmatic empiricism attribute to ailments of the womb. They are, in the usual order of their frequency, *great weariness*, and more or less of *nervousness*, and of *wakefulness*; inability to walk any distance, and a bearing-down feeling; then headache, napeache, and backache. Next come scant, or painful, or delayed, or suppressed menstruation; cold feet, and an irritable bladder; general spinal and pelvic soreness, and *pain in one ovary*, usually the left, or in both ovaries. The sense of exhaustion is a remarkable one; the woman is always tired; she spends the day tired, she goes to bed tired, and she wakes up tired; often, indeed, more tired than when she fell asleep. She sighs a great deal, she has low spirits, and she often fancies that she will lose her mind. Her arms and legs become numb so frequently that she fears palsy or paralysis. Nor does the skin escape the general sympathy. It becomes dry, harsh, and scurfy, and pigmentary deposits appear under the eyes, around the nipples, and on the chin and forehead. Blonds are likely to get a mottled complexion, and brunets to be disfigured by brown patches, or by general bronzing. Sometimes the whole complexion changes to a darker hue, and an abnormal and a disfiguring growth of hair appears on the face. There are many other symptoms of nerve-strain, but since they are not so distinctly uterine in expression, and, therefore, not so misleading, I shall not enumerate them.

Now, let a nervous woman, with some of the foregoing symptoms, recount them to a female friend, and she will be told she has "womb-disease." Let her consult a physician, and he, especially if she has backache, bearing-down feelings, an irritable bladder, and pain in the ovaries, will assert the same thing, and will diligently hunt for some uterine lesion. If one be found, no matter how trifling, he will attach to it undue importance, and treat it heroically as the erring organ. If no visible or tangible disease of the sexual organs be discoverable, he will lay the blame on the invisible endometrium, or on the unseeable ovaries, and continue the local treatment. In any event, whatever the inlook or the outlook, a local treatment more or less severe, is bound to be the issue.

Yet, these very exacting symptoms may be due wholly to nerve-strain, or (what is synonymous) to loss of brain-control over the lower nerve-centers, and not to direct or to reflex action, from some supposed uterine disorder. Neither, for the matter of that, may it come from some real, tangible, and visible uterine lesion which positively exists. Thus it happens that a harmless anteflexion, a trifling leukorrhea, a slight displacement of the womb, a small tear of the cervix, an insignificant rent of the

perineum, or, what is almost always present, an ovarian ache, each plays the part of the will-o'-the-wisp to allure the physician from the bottom factor. To these paltry lesions—because they are visible, palpable, and ponderable, and because he has, by education and by tradition, a uterine bias—he attributes all his patient's troubles; whereas a greater and subtler force, the invisible, the impalpable, and the imponderable nervous system, may be the sole delinquent. The sufferer may be a jilted maiden, a bereaved mother, a grieving widow, or a neglected wife, and all her uterine symptoms—yes, every one of them—may be the outcome of her sorrows, and not the outcome of her local lesions. She is suffering from a sore brain, and not from a sore womb.

Fortunately for my own reputation and for that of my medical brothers who have thus erred, this grave error of diagnosis is not without excuse. For, as has been shown, the symptoms of nerve-strain—the reflexes of grief, of love, of neglect, of remorse, of jealousy, and of unrest—so closely simulate those of even coarse uterine lesions that the nerve mimicries very readily may be mistaken for the symptoms of actual organic disease. Nor, indeed, are they always distinguishable the one from the other, for the marvellous kinship between mind and matter is a tangled skein unravelled yet by dead-house or by laboratory.

Let me illustrate this: Some years ago a healthy lady, aged twenty-three, was engaged to a gentleman whom she tenderly loved. The wedding day was named, the clergyman was notified, and the invitations were sent out. Three days before the one fixed upon for the marriage there came a letter from the man breaking off the engagement. The blow to her love and to her pride was, of course, great. She secluded herself in her room, and in a few days took to her bed with many symptoms of nerve-prostration, of which dysuria and an irritable bladder were the most prominent. For these vesical symptoms she was treated by the family physician with external and internal electricity and with repeated flushings out of the bladder. Getting no better, but steadily worse, the next year she fell into the hands of a specialist who diagnosticated anteflexion of the womb, cervical erosion, and fissure at the neck of the bladder. He dilated the urethra, washed out the bladder, and treated the womb *secundum artem*. Still remaining an invalid, she consulted a third physician six months later. He also dilated the urethra, examined the bladder with the endoscope, washed it out repeatedly, applied electricity to it by an internal electrode, and gave cold douches. No improvement following this treatment, she called in a fourth physician. He kept her several weeks under his care, dilated her urethra, and treated her mainly with electricity if I remember correctly, but of this I am not absolutely sure. At any rate, she was not made a whit better, and a fifth physician was summoned. He without success treated her for anteversion of the womb and rectal ulcer. She now saw her sixth physician. By this time her urethra had been dilated so frequently that, in the examination, his finger entered the meatus urinarius, and, not at first recognizing his mistake, he remarked upon the extreme narrowness of the vagina. He recommended the formation of a button-hole fistula in the urethra, but this advice was rejected. Four years after the beginning of her disorder she returned to the second physician whom she had previously consulted. After treating her heroically for some time without the slightest benefit, he proposed the excision of the bladder. This operation was refused, and she, one year later, drifted back to her sixth physician. He first made a button-hole fistula in the urethra. This failing to do any good, an artificial vesico-vaginal fistula was next tried. No benefit accruing from this operation, her ovaries, as the last resort, were removed, but peritonitis set in and she died. Now, what is the true interpretation of this sad case? The terrible shock to her pride and to her affections shattered her nervous system, and she was suffering more from the reflexes of a sore brain than from a sore bladder or from sore ovaries.

One more example for illustrating the influence of the mind over the body: A lady, after receiving the sudden news of her sister's death, began at once to throw up her food. Despite all remedies prescribed by the family physician, the vomiting persisted so stubbornly that she lost flesh, became weak, and menstrual disturbance set in. A consultant, recognizing the neurotic character of the disease, wished to treat it accordingly. Yet so impressed was she and her relatives by many so-called uterine symptoms, which they attributed to some disease of her reproductive organs, that they laughed at his diagnosis and dismissed him. Two specialists, therefore, were summoned separately, and each one independently of the other attributed the vomiting and her other symptoms to a tear of the neck of the womb, and advised an immediate operation. For this purpose she went to the private hospital of one of these gentlemen. Directly after her admission she was seized with such violent and uncontrollable vomiting that in a few days her life was in danger. First one eminent physician and then another was called in by the specialist, and the three were in constant attendance until, after a desperate illness, she became well enough only to be carried home. No operation whatever had been performed upon her cervix, for she had been too dangerously ill and was still too ill. She was now placed in the hands of her first consultant, who treated her nerves and her nerves only. Under this treatment she became well, wholly well, and has continued well ever since, although the cervical tear still exists. In one word, it was the old, old story of wounded nerves counterfeiting a wounded womb.

Strange as it may seem, the coccygeal joint is very liable to play the barometer to any kind of mental worry. The serious surgical blunder is, therefore, not infrequently made of extirpating for sheer hysterical coccygodynia this important bone, important from its muscular origins and insertions. I have known coccygodynia to attack a lady after the death of her mother. Every kind of treatment failed; but it was finally abruptly cured by her great resentment at the second marriage of her father.

The late Dr. Fordyce Barker told me of an analogous case caused by the sudden death of the gentleman to whom the lady was engaged. After consulting without benefit the best specialists at home and abroad, she led a sofa-ridden life, and did not stir from her house. She obstinately objected to surgical intervention, and the case seemed a hopeless one; but she was permanently cured by a lawsuit following a bitter family quarrel, in which she took a very active part. I have

not on my conscience the extirpation of a nervous coccyx, but this exemption is merely a piece of good luck, and not of good sense, as the following history will show: A highly intellectual lady, among many nervous symptoms suffered much from her coccyx. This she attributed to injuries sustained while she was riding a bucking horse. She was the patient of an eminent neurologist, who had cured her of all her symptoms but the coccygeal one. I was called in by him, and, after doing my best by topical applications, and by replacing a retroverted womb and dislocated ovaries, made up my mind that the trouble was a traumatic one needing surgical relief. The day and the hour of the operation accordingly were fixed upon; but before they were reached the pain mysteriously left the coccyx, never to return. A dominant mental impression—the fear of the operation—exorcised the coccygeal demon.

Once I was asked by a medical friend to see an exceedingly bad and acute case of pruritus vulvæ; the very worst that ever came under my observation. The lady was tossing about in her bed in a state bordering on frenzy from the intense itching, which could be allayed only by cold starch poultices applied every few minutes. Very naturally attributing it to uterine disease, my friend had discovered a small but angry-looking tear in the cervix, exuding a viscous discharge, and I was called in to the case to decide the question of an operation. I, too, was at first led astray; but the suddenness of the seizure, its vehemence, and the lack of consistency in the behavior of the symptoms, put me on my guard, and we soon found out the cause to be an attack of jealousy. This was a stubborn case to manage, but she ultimately recovered under isolation, massage, and heroic doses of asafetida.

Twice I treated a highly intellectual lady for attacks of pruritus vulvæ and of vaginismus. The itching was intolerable and the sensitiveness of the genitalia so acute as to forbid every attempt at sexual intercourse. Each attack was brought on by mental overstrain, from exacting literary work, and much domestic unhappiness ensued. Several cases, I have personally known, of ladies who had for months been treated for supposed uterine or ovarian disease, when their whole and only trouble was remorse at having had illicit intercourse or at having resorted to criminal abortion. I could spin out to an interminable length this list of cases illustrating the close and often very perplexing kinship between the brain and the reproductive organs, but time and space forbid, and these will suffice amply for my purpose.

For such cases as the foregoing ones moral therapeutics are needed, and we may here take a lesson from the ancients. They, recognizing the influence of the mind upon the body, successfully used incantations concurrently with medicines. Savages imitate them by their herb teas and sweat baths, made mysterious by the powwows of the wizard and by the thaumaturgic pranks of the medicine-man. The incantations used by civilized nations at the present day—and I name them with all reverence—are alms, vows, spells, charms, pilgrimages, exorcisms, Christian science, the faith-cure, the laying on of hands, and other like forms of moral therapeutics, which unquestionably have cured and will cure so long as they produce dominant impressions. The legitimate incantations of medical therapeutics are now pretty much limited to distractions, diversions, to travel in foreign lands, to isolation, to hypnotism, to massage, to electricity, and above all to the personal magnetism of the physician, however exerted, for this is the kernel of the treatment and the greatest of all incantations.

Sometimes in these cases an operation acts the part of an incantation. The dread of the knife and the shock of the operation distract the mental attitude of morbid concentration; while the enforced rest in bed gives a chance to the worn-out brain to regain strength and to assert its supremacy over the mutinous lower nerve-centers. This leads me to think that in a large majority of operations upon trifling tears of the cervix, and on incomplete lacerations of the perineum, the good which may accrue comes less from the repair of those organs than from the mental distraction and the enforced rest. But this kind of incantation—the surgical variety—does not always work well; indeed, it often, very often, makes matters worse. One striking example was that of a lady who saw her only child run over and beheaded by a locomotive. Her health began at once to fail, and she took to her bed with the hackneyed symptoms of weariness, wakefulness, a bearing down, an irritable bladder, and many other canonical uterine reflexes. These were attributed by an excellent and a conscientious physician to a torn cervix and to a torn perineum, which were accordingly repaired. But the added shock of the two operations made her very much worse. For these reasons I must confess to becoming far less inclined than formerly to operate on trifling lesions of the reproductive organs, and especially on small tears of the perineum, the repair of which is painful, unnerving, and generally of doubtful expediency. I have become very skeptical of the influence of such lesions upon the general health, and have come to the belief that even in bad cases it is greatly overrated. In my experience the mistake usually made in these cases is that of attributing to the lacerations the mock uterine symptoms of nerve-prostration. About this there can be no error, for I have over and over again, without any surgical treatment whatever, cured of all their ailments patients who had been sent to me for the very purpose of undergoing some operation on the womb, on the perineum, or even on the ovaries themselves.

Just as headache does not necessarily mean brain-disease, so ovary-ache, groin-ache, and backache do not necessarily mean ovarian disease. Nerve-strain and these aches are, it is true, correlatives, but the middle term which connects them is merely a disturbance in the circulation. Yet, time and again—and I say this deliberately—have ladies been sent to me to have their ovaries taken out, when the whole mischief had started from some mental worry. Their ovaries were sound, but their nerves were not, and no operation was needed for their recovery. The physician of the present day is too apt to jump from any distinctly female ache to an ovarian conclusion without the delay of any misgivings. The ache is in the back, then, he argues, it probably is ovarian; it is in the groin, then, of course, it is ovarian; it is in the head, but extremes meet, and surely it comes from the ovaries. I, indeed, have seen a painful nose and also a red one, attributed to the ovaries and treated canonically by the hot vaginal douche and uterine applications. From this widespread bias and pernicious

haste the removal of the ovaries has degenerated into a busy industry by which, in city and in country, very many women have been and are being mutilated, both needlessly and on the slightest provocation.

So misleading, indeed, are the symptoms of a jaded brain or of other nerve-strain, under the uterine guise in which they often masquerade, that when a jilted girl, a bereaved mother, or a grieving wife, consults a physician, he, unless on his guard, will be more likely to minister to a womb diseased than to a mind diseased. Such cases, even when associated with actual uterine disease, are not bettered by a merely local treatment. Nor are medicines by themselves of much avail. What they need are the incantations of the rest-cure, viz., massage, electricity, and strict seclusion. Hope should be infused into every case, and above all there should be imported into it the personality of the physician. The riper my experience the more am I convinced that in the treatment of woman's diseases the possibility of a nerve-origin or of a nerve-complication should be the *fore*-thought and not the *hind*-thought of the physician.—WILLIAM GOODELL, M.D., *in University Medical Magazine.*

PHYSIOLOGIC CHEMISTRY.

To physiologic chemistry, then, belongs the future. Closely related as it is to physiology, pathology, bacteriology, and general biology, it will tend to overshadow these, and the number of its students will be greatly reinforced from the ranks of those endowed with scientific curiosity, for, in one of its branches, that of the physiology and chemistry of the cell, a subject now developing into prominence, the investigator stands face to face with the mother of mysteries, and there is no student who would not give a lifetime of work to be able to lift a corner of the veil to behold her features.

In therapeutics, physiologic chemistry will be a modifying factor. At present we search the whole earth through for drugs to add to our list, and we discover new ones in our laboratory. Those that we take ready-made from Nature, as, for example, quinin, digitalin, etc., are, for the most part, excreted products of vegetable metabolism, whose presence and retention in the vegetable cell, like that of the nitrogenous products in the animal body, are injurious to life. In other words, we use the excreta or by-products of one kingdom to irritate or stimulate the organism in the other. Unless we believe that Providence ordained that vegetable organisms should produce such compounds to touch with exactness the springs of life within us, we may be excused from considering many of them as permanently placed in our Pharmacopeia. Were all the therapeutists of the present day to search for a drug which would benefit cases of pancreatic diabetes, would they ever find one which would replace exactly that physiologic compound whose absence in disease of the pancreas is the cause of the appearance of sugar in the blood? Is it possible to find a by-product of vegetable metabolism which will replace, when the thyroid gland is diseased or atrophied, that physiologic compound whose formation and presence in the normal thyroid gland prevents that deposition of mucin in the body which characterizes the disease myxedema? These facts and the possible advances in our knowledge of physiologic chemistry suggest how transient is the present character of our Pharmacopeia. At the present day we indulgently smile when an old wife gives a child a dose of castor oil or calomel for toothache, knowing how very indirectly the toothache is alleviated, if at all; but what a large number of drugs we employ whose action, contrary to what we suppose, may be as indirect as that of calomel in toothache!—PROFESSOR A. B. MACALLUM, Inaugural Lecture, University Medical Faculty, Toronto, October 3, 1893.

REVIEWS.

MANUAL OF BACTERIOLOGY, FOR PRACTITIONERS AND STUDENTS, WITH ESPECIAL REFERENCE TO PRACTICAL METHODS. By DR. S. L. SCHENK, Professor Extraordinary in the University of Vienna. Translated from the German (by the Author's permission), with an Appendix by W. R. DAWSON, B.A. M.D., Univ. Dubl., With 100 illustrations, partly colored. Pp. 310. London: Longmans, Green & Co., 1893.

THE rapidity with which new text-books on bacteriology are published is nearly equalled by the promptness with which those of Germany and France are presented to English and American readers in English dress. The volume before us is above the average in usefulness, and Dr. Dawson deserves credit for giving us an English version of Schenk's valuable treatise, rather than a new book of his own. For some ten years past it has been quite the proper thing for young medical men, after having taken a few months in foreign laboratories, to perpetrate on an unsuspecting and long-suffering public their more or less crude ideas of the "Essentials" and "Principles" of Bacteriology. It is time the fashion changed. Bacteriology is now old enough to furnish men and writers of experience, and young medical men would do well to follow the excellent example set by Dr. Dawson, in giving place and extended opportunity to the work of an experienced teacher. We have been accustomed to regard Prof. Schenk's book, in the original, as one of the best guides to the science of bacteriology for the physician and student. In its English dress it has lost nothing of its practical character and admirable plan, and has gained considerable in the notes and appendix of the translator. Numerous microörganisms, besides pathogenic bacteria, have received attention, the section on parasitic *protozoa* being particularly valuable, especially the references to their relation to carcinoma as the pathogenic significance of low forms of animal life has been to a considerable extent lost sight of by practitioners in the midst of the continuous fusilade kept up by bacteriologists.

In the course of translation Dr. Dawson has not always improved upon the involved sentences of the original German, and a number of minor errors are apparent to the finical critic; but the book is, on the whole, a good one.

ELECTRICITY IN DISEASES OF WOMEN, AND OBSTETRICS. By FRANKLIN H. MARTIN, M.D., Professor of Gynecology, Post-Graduate Medical School of Chicago, etc. Pp. 278. Chicago: W. T. Keener Company, 1893.

THAT electricity occupies an important place in therapeusis cannot be gainsaid, but that it is to be the pana-

cea that was fondly anticipated a few years ago, not even the least conservative can hope now. In fact, its utility as a therapeutic agent is daily becoming more restricted, and particularly has this been observed in the special line of the gynecologist. Dr. Martin's book, while unquestionably an able, and we must admit, a conscientious *résumé* of applied electricity in gynecology, is still sadly behind the times, and in addition contradictory in many points. For instance, in speaking of electro-puncture for fibroids of the uterus, on page 144, he says: "It should never be resorted to except in otherwise hopeless cases, cases in which the Battey-Tait operation or hysterectomy do not offer an average chance of success in the hands of expert operators," while on page 171 he very kindly admits that in the treatment of fibroid tumors of the uterus "there is still room for the scalpel," and goes on to say, that "about 75 per cent. of all fibroid tumors of the uterus, however, because of electricity should never be touched with a knife." What more direct contradiction than this! In these days of the scientific practice of medicine what can be meant by the term symptomatic cure? (Note pages 153, 155, 158, etc.) Surely the words *metritis* and *hyperplasia* cannot in anyway be construed as synonymatic, and yet we read on p. 190, "metritis and hyperplasia is caused, etc." While condemning the employment of electro-puncture in the treatment of extra-uterine pregnancy, the author recommends the application of galvanism for the same purpose. The distinction, to say the least, is fine, for in either case a dead product of conception is left in the woman's peritoneal cavity, subjecting her to the possibilities of septic absorption and peritonitis. Such a method of treatment can be neither scientific nor safe. A few illustrations like these must suffice. To render Dr. Martin due justice we must admit that his statements are much more conservative and moderate than those of most of the medical electricians of the day.

A MANUAL FOR BOARDS OF HEALTH AND HEALTH-OFFICERS. By LEWIS BALCH, M.D., Ph.D., Secretary State Board of Health of New York, etc. 12mo, pp. 242. Albany, N. Y.: Banks & Bros., 1893.

A VERY useful purpose has been accomplished by the compilation of this manual for health-boards and health-officers in the State of New York, in furnishing a practical guide for the use of all those engaged in the administration of the public health laws. One of the objects of the organization of State boards of health is the encouragement and supervision of the formation of local boards of health, so as ultimately to bring the entire State under local sanitary government, after the plan adopted in England with such good results. When these local organizations have been established, it is of the highest importance that they be governed by well-defined rules and regulations, so that there shall be uniformity of practice and concert of action. In conducing to this important object, the publication of Dr. Balch's manual is most opportune. It is also a useful book in the hands of the public, as it abounds in information upon subjects in which all are more or less interested. Whilst this book is an exposition of the public health laws of New York, and is designed more especially for use in that State, it may be consulted with profit upon matters of general sanitary law and practice which are applicable everywhere, and are not restricted by State lines.

It would be well if a book of this kind were published in every State, not only for its value as a manual for daily reference in administering sanitary affairs, but also for the assistance it will furnish in organizing local boards of health, and in guiding officials after organization has been completed.

CHIRURGIE DES VOIES URINAIRES. ÉTUDES CLINIQUES. Par le DR. E. LOUMEAU, Professeur Libre de Clinique des Maladies des Voies Urinaires, etc. Deuxième édition, revue, augmentée et accompagnée de cinq planches hors texte noires et chromolithographiées. 8vo, pp. 300. Bordeaux: Feret et Fils, 1894.

THIS is a very excellent book, dealing with a subject which has for a few years past been perhaps somewhat too much eclipsed by matters more novel and exciting. It presents a number of graphic clinical histories, with intelligent and well-considered comments. Of these articles, the most elaborate and important is a report of the accidental abscission of a large portion of the urinary bladder in the course of a celiotomy. There are recorded also a number of cases in which hydrocele, due to urethral narrowing, disappeared upon the correction of the latter. Several interesting instances of calculi and other foreign bodies are given.

The author is an advocate of internal urethrotomy in the treatment of stricture; he argues against the retention of a catheter after such operations. Our own experience is decidedly in favor of other methods, in the great majority of cases.

The scientific value of this work is enhanced by its admirable typography and by the beauty of the illustrations.

THE BACTERIAL POISONS. By DR. N. GAMALEÏA. Translated by E. P. HURD, M.D. (The Physicians' Leisure Library.) Detroit: Geo. S. Davis, 1893.

DR. GAMALEÏA has written a very interesting and readable little book, which we have read with a great deal of pleasure. He traces briefly the history of the study of bacterial poisons, and refers to the various theories successively advanced and abandoned. The latter half of the book is devoted to the consideration of the toxic principles discovered in tetanus, diphtheria, cholera, tuberculosis, and other diseases, and to the facts which have been learned regarding immunity and immunization.

TRANSACTIONS OF THE MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND. Ninety-fourth Annual Session, held at Baltimore, Maryland, April, 1892. Also Semi-Annual Session, held at Rockville, Maryland, 1891. Baltimore: Griffin, Curley & Co., 1892.

THIS report has suffered from two causes. In the first place, "on account of the scarcity of funds," it was decided "to omit the publication of all papers read before the Society, except the address of the President and the Annual Oration"; and in the second place the Annual Oration has failed of publication because "after a half-

dozen ineffectual efforts to obtain the manuscript of the annual orator they (the Publication Committee) despaired of their efforts." The result is that we have presented a transcript of the minutes of the two meetings and reports of officers and committees, together with the interesting and instructive address of the President, Dr. Wm. H. Welch, on "The Etiology of Acute Lobar Pneumonia Considered from a Bacteriological Point of View," which is a characteristically complete and reliable record of our knowledge upon this important subject.

Transactions of the American Electro-therapeutic Association. Second Annual Meeting, held in New York, October 4, 5, and 6, 1892.

No place or date of publication is given to this 12mo paper-covered book of 267 pages, and the table of contents is called an "index." There is no index. The contents show earnestness and enthusiasm on the part of some contributors, and on the part of others equal earnestness with more scientific knowledge and greater reserve. The subject to which the reviewer turned with greatest interest, is the important but very obscure one of that phenomenon variously termed "electric osmose," "kataphoresis," "anodal diffusion." We cannot say that any of the difficulties have been cleared away by the discussion, which is, however, entertaining and contains a few facts of genuine importance. The Association is doing good work, and after awhile, when its business committee feels strong enough to exclude unscientific and unbalanced contributions, its work will be still better. We cordially wish it success.

Mechanical Aids in the Treatment of Chronic Forms of Disease. By George H. Taylor, M.D. New York: George W. Rodgers, 1893.

The subject-matter of this little brochure of 109 pages is presented in five chapters: the first is taken up with a description of a postural or "lifting couch," the rationale of its mechanism and the indications for its employment; the second chapter deals with a chest-developer and its therapeutic uses; the third chapter takes up massage—its principles, varieties, factors, and adaptations; the fourth treats of the therapeutics of slow massage, auto-massage, and kneading; and the fifth presents the therapeutics of rapid (mechanical) massage, with a consideration of its different forms and effects.

Transactions of the Fourth Annual Meeting of the Medical Society of the State of Washington, held at Tacoma, May 3, 4, 5, 1893. Spokane: Willcox Printing Co., 1893.

This brochure of 153 pages is an indication of how far West progress has advanced, and reflects credit upon a body which, in the fourth year of its existence, has attained a membership of 110. The *Transactions* contains, in addition to the official report of the proceedings of the fourth annual meeting, sixteen papers on diverse interesting subjects. The regard in which the Code of Ethics is held is shown by its publication unabridged.

Hernia: Its Palliative and Radical Treatment in Adults, Children, and Infants. By Thomas H. Manley, A.M., M.D., etc. 8vo, pp. 231. Philadelphia: The Medical Press Co., Limited, 1893.

We find in this book absolutely nothing that is new; it is written in a style at once bombastic and slovenly, and is full to overflowing with errors of syntax, punctuation, and spelling, many of which are obviously not chargeable to the printer. It contains sixty-four woodcuts of various degrees of badness.

Medical News Visiting-list for 1894. Philadelphia: Lea Bros. & Co.

This familiar and standard visiting list appears annually in an improved form. The edition for the coming year, among many other attractive features, contains a catheter scale graded according to both the French and American systems, and a dose-list that includes all of the old and many of the newer remedies, such as sulfonal, ichthyol, and bromoform, that have survived the rigorous test of clinical experience.

The Physicians' Visiting-list for 1894. Philadelphia: P. Blakiston, Son & Co.

This standard visiting-list has been revised for 1894, and, besides the usual spaces and arrangement for visits, contains many valuable tables, memoranda, and convenient and useful helps for the busy physician.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

November 7, 1893.

A CASE OF MALARIAL HEMATURIA AND ONE OF LEUKEMIA.

Dr. Whittaker presented first a case of hematuria, the obtrusive symptom being that the patient passed blood in his urine. He suffered in this way, he says, a number of years, and finally came to look upon the condition as an incurable malady. The urine showed an unusual amount of blood, and the patient, though a large man, was profoundly anemic. I at once entertained suspicion that it was a case of malaria, but though the patient declared that he had never had malarial fever, that is, that he had never had chills and fever, we examined his blood and found in it absolute evidence of malaria. We put him upon quinin and the hematuria began to disappear.

The case is exceedingly interesting as showing the exactness with which a diagnosis can be made from a drop of blood. I have also here three specimens of the urine. The tube on the extreme left contains urine discharged when he first presented himself; the tube in the middle, urine after treatment for one day, and the tube on the right, urine after treatment for two days. The first tube is black, the second brown, the third yellow. I do not wish to take up the time of the Academy with this case, for I have here one of even greater interest.

This gentleman was sent to my surgical confrère, Dr. Ransohoff, to be operated upon for the relief of an abdominal tumor. His history can be epitomized as one

of abdominal tumor with progressive marasmus. The patient became aware of the tumor and of the weakness at about the same time—in March, about eight months ago. The tumor was a mass in the left side of the belly. When I saw him first, a few days ago, he showed about the same appearance as to-day. Strange to say, he has rather the hue of health, and no one would consider him anemic. His face is full, the veins about the temple rather over-full, and his expression is cheerful. This tumor, which fills up and distends the left side of the abdomen, is very hard, yields no fluctuation, and bulges below. It seems to be the spleen. There is also a tumor in the region of the liver, which is apparently an enlargement of this organ. The lymphatics in the neck and groin are slightly yet distinctly enlarged. The patient has felt no pain in the region of the spleen, nor has he experienced any discomfort, except that connected with the mere fact of distention. There is no tenderness even on pressure. The legs show abundant pigmentation. The patient seems to be truthful, and he declares that he has had gonorrhea but has never had syphilis. Interrogated about hemorrhage, he recalls the fact that he had nose-bleed several times, first a year or so ago, and occasionally since.

In explanation of the tumor we had to consider syphilis, sarcoma, and leukemia. All that spoke in favor of syphilis were these spots on the legs. There was no other evidence to be found, unless the adenopathy could be so considered. Sarcoma could not be so lightly dismissed. The diagnosis of leukemia was favored by the history of nose-bleed and the enlarged glands of the neck and of the groin, the latter perhaps not more than twice their natural size. Against this diagnosis is the apparently healthy hue and condition of the man. It was, of course, impossible to go further into the study of the case without an examination of the blood. This examination was made by Dr. Greiwe, and he will report upon the condition, and show you some beautifully-colored specimens, after which, with the permission of the Academy, I shall continue my report.

DR. GREIWE said: The count of the red and white blood-corpuscles of this patient with the hemocytometer showed that there were only 2,480,000 red, the proportion of the white to the red being 1:3, whereas most writers give it as 1:355, and some 1 to over 800. Microscopically, the blood was not very pale, but it was sticky; the microscope showed that the vast majority of the white cells were the small leukocytes, next the large leukocytes, numerous eosinophile cells, blood-plates, and numerous nucleated red blood-corpuscles. One specimen is under the microscope, which verifies the diagnosis of leukemia. The white blood-corpuscles have been stained, and the red are only faintly outlined.

The report of this case shows not only enlargement of the spleen, but also enlargement of the liver; and, owing to that fact, I have brought down a specimen of a patient who died in Berlin of leukemia within eleven days from the onset of the trouble. I reported that case in the *Berliner klinische Wochenschrift*, and believe the history proved the case to be of long standing, although the patient considered himself perfectly well, until he was compelled to go to bed. In that case the spleen was enlarged as much as in this one. It had been diagnosticated as scurvy, but it proved to be a most remarkable case of lymphatic leukemia. Some authors have denied that it is possible, from staining the blood, to distinguish the various forms of leukemia, that is, whether it is splenic, lymphatic, or myelogenic, whereas others claim that it is possible from an examination of the blood to determine, from the character of the cells, which organ is most involved. Thus, one case that I reported was examined and pronounced one of lymphatic leukemia, although the enlargement of the lymphatic glands was very slight indeed. In another case I reported, in Berlin, the spleen extended into the pelvis, and could be distinctly outlined on the right side. That case, although it would likely be called splenic leukemia, showed all the features of the disease starting from the marrow of bone. The cells were characteristic of that. In this case, according to the statements of Ehrlich, Jaksch, and others, I should judge it to be a mixed form, that is, arising from both the spleen and lymphatic glands; but from the character of the cells, however, I would say the lymphatic glands are most involved, although the enlargement of the spleen is more marked than that of the lymphatic glands. The increase of the white cells is mainly due to the small leukocytes, and, next, to the large leukocytes. Some have a double nucleus, others a large nucleus. In making a diagnosis of leukemia from an examination of the blood, it is very important to bear in mind the character of the cells. There are cases that very closely resemble leukemia and yet are quite different. The cells of leukocytosis usually have more than one nucleus. That is characteristic of leukocytosis, and not of leukemia. The diagnosis is made from the abnormal increase of those which are not multinuclear.

DR. DEBECK: Upon examining the patient's eyes this afternoon, I found the fundus not especially pale; neither was I able to obtain the characteristic orange-yellow tint with the ophthalmoscope. That may be due to using ordinary gaslight, for I was not able to examine him by the electric light or by daylight. Both eyes show a neuro-retinitis. The arteries seem but slightly, if at all, narrowed, but the veins are considerably enlarged and exceedingly tortuous. The exudation is such that at many points the vessels are quite obscured. Particularly in the region of the disc I noticed the streaked appearance of the fundus which is characteristic of neuro-retinitis; but what is very characteristic in this case is the presence of minute hemorrhages. These are very striking, running along the course of the nerve-fibers. There is a peculiar condition to which attention has not before been called, with which we are perfectly familiar in embolism of the central artery. This is the cherry-red spot at the macula. It is probably simply a contrast appearance, the thin *fovea centralis* allowing the red to show through, and this appearance is heightened by the blurred retina about the macula. In the region of the right macula there are some larger hemorrhages, and just at the edges of the right disc is one of the characteristic minute round glistening spots to which attention has been called. The whole condition taken together gives quite a typical picture of leukemic neuro-retinitis, to which attention has been called by Liebreich, and of which a very excellent drawing is given in his *Ophthalmoscopic Atlas*.

With all of these changes vision in each eye is little below normal, although it is not 20/xx sharp.

4976

Dr. Stricker: I am very happy to have seen the fundi of this man's eyes, for I have never known a similar case, although I have read considerable on the subject and seen many ophthalmoscopic pictures. One feature, by which alone a diagnosis could have been made, is the hemorrhages. These take on a peculiar form, entirely different from that seen in any other form of hemorrhage, namely, a red ring with a white center; the white corpuscles congregate in the center, while the red corpuscles form a ring around them.

Dr. DeBeck has spoken of the cherry-red spot, seen in cases of embolism, directly in the macula. This is a contrast-effect due to the pallor of the retina, the red, shining through at the thin macular region, being due to the choroidal circulation. Here in the case before us the condition is quite different. There is an actual diapedesis of the corpuscles, white and red, through the vessel-walls, and it has never been properly explained why, in this form of disease, they should arrange themselves so peculiarly, all the red surrounding the white, which are grouped together. All this is found in no other ophthalmoscopic picture, and when seen is pathognomonic.

The papilla likewise shows a peculiar and interesting condition. It is swollen, edematous, and in many places covers the vessels which pass out from it; but, above all, it has a paleness that is never present in papillitis. This is likewise due to exudation of large numbers of leukocytes, which have caused the swelling of the papilla and give it its peculiar choked appearance.

Dr. Kramer: With this blood there can be no doubt of the diagnosis of leukemia, but I would like to suggest sarcoma of the spleen as a possible cause of the leukemia. A number of cases of so-called idiopathic leukemia have upon post-mortem examination revealed sarcoma of the spleen. I particularly recall a case of well-marked leukemia that occurred in the service of Dr. Forcheimer at the Children's Hospital almost six years ago. Transfusion was practised in this case with no benefit, and post-mortem examination revealed multiple sarcoma of the spleen. I think a little weight would be lent to this diagnosis in the present case by the size of the tumor, and I should like to have the gentleman who presented the case discuss the differential diagnosis.

Dr. Langdon: The case calls to our mind the exactness with which a diagnosis may be made by means of the microscope and other instruments of precision; still I think we are likely to be misled even with them. The only case of leukemia I ever saw was in consultation with Dr. D. D. Bramble, of this city. Briefly it was as follows: A man, about thirty-two years of age, was suffering with an apparently enlarged spleen. An examination of the blood showed white blood-corpuscles present in the proportion of 1 to 20 of the red. An autopsy in that case revealed a large spindle-celled sarcoma involving the psoas muscle and extending into the spleen, so that it was continuous with it, and the spleen itself was enlarged. The remark by the previous speaker, that these symptoms may be due to multiple sarcomata, recalls the fact that the sarcoma need not be multiple. The tumor in the case I have spoken of was probably as large as a child's head, and a microscopic examination showed it to be a spindle-celled sarcoma. This man had even the spongy gums and the scorbutic tendency, and was markedly anemic, while he did not have the enlarged lymphatic glands. The diagnosis there was leukemia, which was evidently due to irritation of the spleen by the sarcomatous tumor. The tumor was not very movable, but it was quite large and had involved the surrounding parts to a great extent.

Dr. Greiwe: The subject of sarcoma being brought up in this case, I would like to refer to a case reported by Dr. Ayres. It was a case of tumor of both orbits, and from an examination of the specimen we concluded that it was a form of sarcoma. While I was looking up the literature of that case I came across the report of a case by Dr. Dock, of Ann Arbor, who found a distinct leukemia a few days before death, with all the characteristic appearance of white corpuscles in the blood. In this connection it remains to be said that the true nature of leukemia is entirely unknown. By some it has been referred to as a sarcoma of the blood.

Dr. Ransohoff: It was supposed in this case that the kidney was affected. I found that it was the spleen, and believed the case one for the medical clinic. Subsequently I looked at the spots referred to rather carefully, and they impressed me as not like the spots from poison-oak or ivy, but rather like those due to syphilis. The man had a number of these scars on his arms, and he also had enlargement of the posterior cervical glands, which is so characteristic of latent syphilis. So that, notwithstanding the fact that this patient tells us he has not had syphilis, I am of the opinion that the disease is at least of syphilitic origin. The scars are quite characteristic, and the fact that he has improved on potassium iodid leads me to believe the syphilitic theory is justifiable. We still, to a certain extent, must rely upon therapeutic tests. Sarcoma, I agree, is possible, but I think it hardly probable. In the first place, it is a very rare condition in this situation, and then we hardly expect to find so uniform an enlargement. The spleen usually has one or two notches in its border, and despite its enlargement these can usually, indeed almost invariably, be felt. I have never been able to find them in the patient. If it is a sarcoma and not a leukemic spleen, it, of course, should be operated upon, and the sooner the better. Cases have been reported in which complete recovery has followed removal of the spleen. If this is a leukemic spleen, of course, operative interference is out of the question. Patients usually die after the removal of a leukemic spleen. They die from the shock, and perhaps half of them die on the table. I think, in fact, only one case has been reported which recovered after the removal of a leukemic spleen, and even this has been doubted.

Dr. Whittaker: We have now had the whole subject illuminated. The diagnosis is made absolute by the examination of the blood, while the symptoms, the epistaxis, spleen-tumor, lymph-abdomen, and marasmus, take their places orderly in the course of this disease. Two allied conditions were mentioned in this study, leukocytosis and pernicious anemia, one a benign, the other a malign process. There is a great difference between a leukocytosis, and a leukemia, and that is the first thing to bear in mind in studies of the blood. A leukocytosis we welcome. It occurs, as a rule, in typhoid fevers and in pneumonia at the time of the crisis, which it is supposed to bring about by liberating

antitoxins. We try to produce this leukocytosis, artificially if possible, by the process of chemotaxis. A leukocytosis is an increase of the white blood-corpuscles, but by no means to the degree of that of leukemia. One c.mm. of blood contains five million red to from five to ten thousand white corpuscles. This is the normal ratio, but the proportion varies greatly even in health. It may be 1 : 400. It may be even 1 : 50 and not be truly pathologic. It is when the disproportion is greater than this, 1 : 40, 1 : 20, 1 : 10, or as here 1 : 3, that the condition is pathologic. But if we should think that this disease, leukemia, is simply an increase in the proportion of white blood-corpuscles, we make a great mistake. When an individual, the victim of leukemia, is bled, the red blood-corpuscles are restored just as in an individual not leukemic, but only up to the previous number; not to the natural number. That shows us that there is something that affects the whole blood, holding, as it were, the blood-making functions down. Leukemia is, according to the present belief, some kind of an infection. Those studies are interesting that try to show whether the disease arises in the bone-marrow, in the spleen, or in the lymphatic glands. These things have yet, however, not the same interest as the determination of the cause of the condition. One marked change in many of the cells is their immobility. It would appear as if they were dead, while in leukocytosis they are alive. It is said that there is no case in which the bone-marow is not affected, although it is, of course, affected in some cases more than in others. Tenderness of the bone is not noticed even in myelogenic cases. It must be remembered, too, that the lymphatic glands are often affected on the inside of the body and not on the outside.

Pernicious anemia distinguishes itself by poikilocytosis, by deformities of corpuscles, and defective arrangement, as well as by absence of lymphadenoma and tumor of the spleen, and more rapid progressive degradation. Leukemia occurs in the course of malaria, tuberculosis, rickets, syphilis, traumata, anxiety, and depressing emotions, and oftener independently of discoverable cause.

A number of rapid cures of leukemia, hitherto considered incurable, have been reported recently from Scotland, under large doses of arsenic. I will try in order in the treatment of this case, quinin, potassium iodid, methylene-blue, and arsenic, and report the results, or show the patient again.

NEWS ITEMS.

The Association of American Medical Colleges.—At a meeting of the Faculty of Rush Medical College, held December 7, 1893, the following resolution was unanimously adopted:

Resolved, That Section 5, Article III, of the Constitution of the Association of American Medical Colleges be amended to read as follows: "From students who intend to graduate in 1899 or in subsequent classes, four years of medical study and an attendance upon four annual courses of lectures of not less than six months' duration each, will be required. Provided, that graduates of literary colleges who have taken a course of four years, including study in the natural sciences, and graduates from universities and colleges that furnish a suitable course of scientific studies, graduates of schools of pharmacy that require three years of study and adequate preliminary education, and graduates of dental colleges requiring two years of study and adequate preliminary education, may be admitted to the second year's work or course of lectures in the college without examination."

The present wording of Section 5, Article III., is as follows: "Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instruction of not less than six months each, in three separate years."

The adoption of the proposed amendment will require of all matriculates of the session of 1895 attendance upon four full courses of instruction before receiving the degree of M.D.

Recognizing that the proposed amendment, if adopted, would necessitate the formulation of a general curriculum of study for the various branches of the courses, and, perchance, other necessary changes or additions to the by-laws, the President of the Association of American Medical Colleges, Dr. N. S. Davis, has appointed the following-named persons to act as a special committee to prepare a new schedule of minimum of requirements, to be submitted at the fifth annual meeting, to be held at San Francisco, at 3 o'clock P. M., Wednesday, June 6, 1894: E. L. Holmes, Chairman of the Committee, President Rush Medical College, Chicago, Ill.; Reginald H. Fitz, Harvard Medical College, Boston, Mass.; Victor C. Vaughan, Dean Department of Medicine, University of Michigan, Ann Arbor, Mich.; Wm. Osler, Johns Hopkins Medical College, Baltimore, Md.; Wm. E. Quine, President College of Physicians and Surgeons of Chicago, and President Illinois State Board of Health; P. S. Conner, Ohio Medical College, Cincinnati, Ohio; Dudley S. Reynolds, Hospital College of Medicine, Louisville, Ky.; N. S. Davis, Jr., Chicago Medical College; Perry H. Millard, Dean College of Medicine and Surgery, University of Minnesota, Secretary Association of American Medical Colleges, St. Paul.

The committee will hold a meeting in Chicago, at the Grand Pacific Hotel, at 3 o'clock P. M., Wednesday, February 7, 1894. Colleges that are members of the Association are requested to aid the committee in its work by advice or representation. It is particularly desirable that colleges that are members of the Association should be represented by a formally appointed delegate at the forthcoming session. The proposed amendment, if adopted, marks a most important era in the history of medical education in this country. Colleges unable to be represented by a regularly appointed delegate will confer a favor by informing the Secretary of their attitude on this amendment, to be submitted or made known to the convention before final action is taken. Colleges electing delegates are requested to indicate in their credentials if they have full power to act, and to furnish the Secretary the names of the delegates elected as soon as practicable. Colleges are entitled to one delegate each. A proxy cannot be delegated to a person not directly connected with the college desiring representation.

There are at present seventy-one colleges members of the Association of Americal Medical Colleges.

The constitution cannot be altered or amended except

after written notice to all the members at least thirty days previous to a stated meeting, and by a vote of two-thirds of all the delegates present at such meeting.

August Martin, heretofore docent, has been made Professor of Gynecology and Obstetrics in the University of Berlin. The honor thus conferred is an eminently deserved one.

Dr. Russell Reynolds has been elected president of the Royal College of Physicians, of London, in succession to the late Sir Andrew Clark.

Books and Pamphlets Received.

A Text-book of Physiological Chemistry. By Olaf Hammarsten. Authorized Translation from the Second Swedish Edition and from the Author's Enlarged and Revised German Edition. By John A. Mandel. First edition. New York: John Wiley & Sons, 1893.

Open-Incision Tenotomy, with Report of a Case in which the Tendon was Sutured by the Anderson Method. By James F. E. Colgan, A.M., M.D. Reprinted from the Therapeutic Gazette, 1893.

ORIGINAL ARTICLES.

THE RELATIVE FREQUENCY OF FIBROID PROCESSES IN THE DARK-SKINNED RACES.

BY EDWARD A. BALLOCH, M.D.,
INSTRUCTOR IN MINOR SURGERY, MEDICAL DEPARTMENT OF HOWARD UNIVERSITY, WASHINGTON, D. C.

IN stating that the color of the skin is but a minor point of difference between the white-skinned and dark-skinned races, one gives expression to a fact that must have impressed itself upon every observer who has had much to do with the two races. One need have but a limited experience in this connection to enable him to note many and important variations, and, while both races have probably developed from the same primitive ancestor, the development has been along different lines, and has resulted in two distinct types. Some forty years ago this matter was the subject of much controversy in the medical journals of that period, but the scientific aspects of the question were obscured by its political and sentimental sides. The time was not then ripe, but I think we have now reached a period when we can consider this question without passion. We have, in this subject, a field of pathology exceedingly interesting, but little worked, and wholly our own. We owe it to ourselves, not less than to science in general, to give a good account of our stewardship in this matter. It is important that this be done now, as, with changed environments and changed conditions, the types of disease are changing, and their characteristics should be fixed as soon as possible.

It shall be my endeavor, in this contribution, to point out a few of the differences between the two races, and to try to show that the characteristic pathologic difference between the two is the remarkable tendency to fibroid processes to which the dark races are subject.

The negro differs from the Caucasian anatomically, physiologically, and pathologically. The comparative anatomy of the two races has never been systematically studied, and it is a matter for congratulation that the Association of American Anatomists has taken this question in hand and has issued a circular asking that practical anatomists give their attention to it, and keep a careful record of all variations and anomalies. Many isolated facts, however, have from time to time been put on record, and these fragments show that much may be expected from a more extended and careful study. It must be premised, however, that the pure negro type is exceedingly rare in this country, and on this account observations as to agreements and contrasts are very difficult owing to the comparative infrequency of typical specimens. The larger the admixture of white blood, the closer the approach in every way to the Caucasian type.

Among others, Parker[1] has noted, in two among thirty-three negro brains examined by him, the existence of an internal *pli du passage*, as well marked as in any of the Simiadæ. This convolution has been uniformly present in all the Simiadæ thus far examined, except two, but prior to Parker's discovery, it had never before been found in man in a fully developed condition, and its absence had been regarded as a distinguishing characteristic of human as compared with anthropoid brains.

Baker[2] regards a perforation of the olecranon fossa, found in South African and other low tribes, as a reversion toward the anthropoids. He also describes bands of deep cervical fascia which alone remain to testify to the former existence of the *levator claviculæ*, a muscle present in most mammals, and one which he has frequently found almost complete in the negro. In the pithecoid apes the rhomboid muscle extends to the occipital bone, and in anthropoid apes to the spinous process of the fourth cervical vertebra (Broca). In a negro of Mozambique, Chudzinski[3] found this muscle to extend to the third cervical vertebra, and in another negro subject to the spinous process of the fourth cervical vertebra. The same observer also notes[4] the presence in the negro of an independent fasciculus to the deltoid muscle, a characteristic of the primates.

The psoas parvus is another muscle present in nearly all mammals except man. Theile considers its absence to be the normal condition in man, stating that he found it only in one of twenty bodies in which especial search was made for it. Holden gives its frequency of occurrence as once in ten subjects. From a considerable experience in the dissection of colored subjects I am able to state that the absence of this muscle in them is the exception, and its presence, on both sides, and well developed, is the rule. There is no difference as regards the two sexes.

The osteologic peculiarities of the negro have been fairly well investigated. The skull is prognathous, with a facial angle of from 65° to 70°.

The parietal bones are thick. The zygomatic arches are wide, and the upper edge of the orbit projecting. The pelvis is long and narrow, the iliac bones less wide and more vertical. The tibia and fibula are more convex, and the os calcis is continued in a straight line with the other bones of the foot. The scapulæ are shorter and broader. The thigh and arm are rather shorter. While the leg is actually about the same in length, it is relatively smaller, owing to less average stature. The forearm is longer, both actually and relatively. The foot is an eighth, and the hand a twelfth, longer than in Europeans. Humphry's tables are as follows:

	European, average of 25	Negro, average of 25	Bosjesman, average of 3	Idiot, in Berlin Museum.
Height	65 inches	62 inches	54 inches	57 inches
Middle point of skeleton,	Symphysis pubis	1 in. below pubis	Symphysis	Symphysis
Length of spine	22.2	19.3	17.0	19.5
Circumference of skull,	20 5	19.8	19.6	13 5
Humerus	12.7	12 1	10.8	12.0
Radius	9.2	9.4	8.3	8.8
Hand	7.3	7.7	6.0	7.0
Femur	17.88	17.0	15.0	16.0
Tibia	14.4	14.4	12.9	12.5
Foot	10.6	11 11	7.5	8.5
Pelvis, transverse diameter of,	5.2	4.6	4.4	5.0
Pelvis, antero-posterior diameter of,	4.3	4.1	3.5	3.8

Or, reduced to a scale of 100:

	European.	Negro.	Bosjesman.	Idiot.
Height	100.00	100.00	100 00	100.00
Length of spine	34.15	31.13	31.48	34.21
Circumference of skull.	31.54	31.94	36.29	23 68
Humerus	19.54	19.52	20.00	21.05
Radius	14.15	15.16	15.37	13.43
Hand	11.23	12.42	11.11	12.28
Femur	27.51	27 40	27.78	28.07
Tibia	22.15	23.23	23.89	21.92
Foot	16.03	17.90	13.78	14.96
Pelvis, transverse diameter of,	8.00	7.42	8.15	8.94
Pelvis, antero-posterior diameter of,	6.61	6.61	6.48	6.66

It is probable that many other anatomic differences between the two races exist, which have escaped observation, owing to lack of attention. My own observation is, that in the negro the brain is relatively smaller, the liver larger, the lung-capacity smaller, and the vascular area greater. Enough has been shown, I think, to demonstrate that the anatomic variations in the colored race are neither few nor unimportant, and it is hoped that, the attention of American anatomists having been drawn to this subject, many new facts may be recorded.

The dominant physiologic peculiarity of the negro is the lessened sensibility of his nervous system. By this is meant a less acute response to external impressions. His ability to resist severe and prolonged exposure to the sun's rays is well known. As has been stated, the capillary circulation in the negro is believed to be relatively greater than in the white, though this belief lacks the confirmation of sufficient and accurate observation. If it be true, it is remarkable that this fact, in connection with a black skin and more numerous sweat-glands, tending as they all do to a more rapid cooling of the body, presents a condition so well adapted to existence in hot climates. The evolutionist will see in this the adaptation of the animal to its environment, and the acquirement of means necessary to resist external factors hostile to its continued existence. On account of this blunted sensibility of the nervous system the negro bears surgical operations remarkably well. He seldom suffers from shock, and wounds of all kinds heal with a quickness and certainty delightful to the surgeon. The mortality from capital operations is remarkably small. Possibly a part of this exemption may be explained on hygienic grounds. The comfort and good food of a well-regulated hospital, to the majority of patients of this class, are a decided improvement upon their ordinary surroundings and mode of life. But this explanation will not cover all cases, and, indeed, this recuperative tendency has been noticed under circumstances where the objection could not be urged. Given a white and a black man, taken, as far as possible, from similar hygienic surroundings, and let each be subjected to a similar operation, say the amputation of a leg, other things being equal, the white man will die and the black recover.

As is well known, the emotional side of the negro is well developed, and there is in him a certain tendency to fatalism which leads him to accept accidents and illness, with all their consequences, as parts of the inevitable, and to be borne without murmuring, as the dispensations of a higher power against which it is useless to struggle. But this trenches on the domain of psychology, and is foreign to the purpose of this essay.

In the matter of susceptibility to disease there is a marked difference between the two races. Of course, they touch at many points, and many of the seeming differences may be reconciled on the ground of different hygienic conditions; but after due allowance for errors of this description, there yet remains a body of fact valuable to the pathologist and anthropologist. My own experience in practice among the two races will warrant the following conclusions:

Tuberculous diseases are rife among the colored people. To such an extent is this true that I now make it a rule to ascribe to tuberculosis any obscure process in them not otherwise determinable. Whenever I have been able to secure post-mortem demonstration in this class of cases I have generally found myself correct in my supposition. Particularly is this true of tuberculous peritonitis. Scrofula numbers many victims, and rickets is not unknown. Pneumonia is exceedingly fatal, a fact first noticed during the late Civil War, and confirmed many times since by numerous observers. Between July 1, 1875, and June 30, 1890, there were reported in the District of Columbia,[5] 1020 deaths from congestion of the lungs. Of these, 521 were among white, and 499 among colored persons. When it is considered that the white population is a little more than twice as large as the colored, the significance of these figures becomes apparent. In other words, had the number of each been equal, the mortality would have been 998 colored to 521 white. During the year 1890 the deaths from pneumonia, in the same locality, numbered 416, of which 181 were among white and 235 among colored, being in the proportion of 1.065 to 1000 for the former and 2.937 to 1000 for the latter. The per mille rate from all diseases of the respiratory organs during 1890 was 1.905 in the white, and 5.175 in the colored, while that from tuberculous diseases generally was 2.558 and 6.825, respectively. These figures speak for themselves.

Hemorrhoids and rectal diseases are very infrequent in the colored race. Diseases of the skin are about as common as in the whites. Also, there is not much difference in the matter of the zymotic diseases. The negro enjoys a remarkable immunity from affections of the nervous system, but according to Witmer and some other authorities, the proportion of insane is increasing rapidly. This is ascribed to the changed conditions under which the negroes are living since the abolition of slavery. It is probable, however, that the lack of accurate statistics before the year 1880 precludes any certain conclusions in this respect, and more time must elapse before generalizations are possible. Chorea is almost never seen, and I cannot recall a single instance of locomotor ataxia in this race. The arcus senilis is very common and is developed early, often at forty years of age. Pterygium is almost universal. Among 138 colored persons examined for this affection I found it in 102.

The negro shows a remarkable freedom from malignant disease. Epithelioma is almost never seen, and carcinoma but rarely. In a recent number of THE MEDICAL NEWS, Kelly notes several cases of epithelioma of the cervix uteri seen in colored persons, one of whom seemed to be a negress of perfectly pure blood. Sarcoma is the most frequent of the malignant neoplasms in negroes, a fact upon which I desire to lay especial stress, and to which I shall allude again later.

These opinions, based on my own observations, coincide in the main with those of such good observers as Tiffany,[6] Briggs, the late Christopher Johnston, and others, as expressed, in 1888, in a paper and in the discussion before the American Surgical Society. The greater facility in the healing of wounds possessed by the colored race has not escaped the attention of foreign observers who have been brought in contact with them. Thus Hillary,[7] an English surgeon who served with the colored troops during the late Civil War, noted this fact as a result of his experience among both classes of troops. After the war, he went to Canada and thence to Jamaica. In the latter locality his experience as to the more rapid healing of wounds in the blacks was confirmed. He also noted the fact that it was necessary to tie a greater number of vessels in an amputation in the case of a black than in the case of a white. After considerable study of the question he states it as his conviction that the circulation in the dark races is more branching and capillary, and that this relatively greater vascularity will explain the greater facility in the healing of wounds. This opinion coincides with my own observations.

Coming now from general to particular considerations, I desire to state as a pathologic axiom that fibroid processes are relatively more frequent in the dark races, so much more so, in fact, as to constitute a racial peculiarity. By fibroid processes I do not mean the physiologic fibrosis incident to advancing years, nor yet that form in which the parenchyma of an organ is encroached upon by an interstitial connective-tissue hyperplasia. I desire to confine the term to those processes the essential characteristic of which is growth, and which for the most part depend upon changes caused by inflammation, and which, as a rule, have some external injury as a starting-point. As the element of heredity seems to enter largely into these changes, perhaps the term "fibroid diathesis" may be admissible as expressing the inherent tendency to this class of changes.

There are three diseases which, by common consent, are considered as peculiar to the dark-skinned races. These are elephantiasis Arabum, keloid, and fibroma, or myo-fibroma, of the uterus. In addition to showing that these are peculiarly diseases of the dark races, I propose to show that they are true fibroid processes, and incidentally to consider their pathology with a view to determining their points of agreement and difference.

That elephantiasis Arabum is a disease almost indigenous to the dark races has been recognized for many years. As early as 1726, Richard Towne,[8]

in the last chapter of his little work, affirms this fact and discusses the pathology. Sir Joseph Fayrer[9] is a different sort of pathologist from Richard Towne, but his testimony is not less emphatic. He states that no race is exempt from the disease, but that the white races undoubtedly suffer less from it than the dark. It does occur, he says, though very rarely, in the pure European in India, more frequently in those of mixed descent, most frequently in the native. He observes that it will frequently be found that when it occurs in persons of apparently European parentage there will be found an admixture, however slight, of dark blood. This is strong language, and, coming from so experienced and careful an observer, should be convincing. But there is other evidence to the same effect. Other English observers who have noted this same tendency are Richards,[10] Hillary,[11] Oldfield,[12] and Daniell.[13] Among American observers, J. B. S. Jackson,[14] in giving an account of his voyage to Barbadoes, alluding to Barbadoes leg, states that it is more common among the blacks, even allowing for the differences in proportion of the two races. Prof. James C. White's[15] opinion is that the black race is especially predisposed to elephantiasis, the growth often attaining an enormous size.

Dr. Rufz[16] was a French physician who resided twenty years in Martinique. During his stay he kept very careful memoranda of all diseases coming under his notice, and being an accurate and skilful observer, his conclusions are worthy of respect. I desire here to express my sense of obligation to his conscientious and exact records, to which I shall have occasion several times to refer. In speaking of elephantiasis he states that it is much more frequent in the negro than in the mulatto, in whom one sees it very frequently, but that he has never seen it in a white person. Levacher,[17] another French physician, has noted the same peculiarity.

It is, however, useless to burden our argument with the further citation of authorities. The testimony is uniform and emphatic as to the great preponderance of elephantiasis Arabum in dark-skinned races, and we are bound to accept it as a fact, explain it how we may. I have notes of five cases seen by me during the past year. Four were in colored persons and one in a white man. In one case the diagnosis was verified by a post-mortem examination.

There is much doubt as to the exact etiology of elephantiasis Arabum. Medical literature is full of articles bearing on this point. It has been described as erysipelas, as a phlebitis, as a lymphangitis, as a disease of the nervous system, and as a result of blocking of lymph-channels due to filariæ. The truth appears to be that many separate processes have been described as elephantiasis. But whatever each may assign as the particular cause, all are agreed as to the result, viz., an enormous increase in the connective tissue. The cuticle may be normal or thickened. When thickened I think the process should be ascribed to mechanical causes, as the epidermis is of epiblastic origin, while the corium is of mesoblastic origin, along with the connective tissue, and as this is purely a connective-tissue growth the epidermis should not, as a necessary consequence, be involved. In most cases the cuticle is normal. As would be expected, the corium is thickened, and contains a tolerable abundance of fine elastic filaments. The subcutaneous connective tissue is enormously developed, and is generally thicker next the derm. The hypertrophied connective tissue consists of yellow and white fibrous tissue, the former being more abundant. It may contain unstriped muscle, arranged in narrow bands, vertically as well as transversely. The sebaceous and sweat glands are generally normal. As Wilkes and Moxon[18] well point out, there is in the hypertrophied connective tissue of elephantiasis no element differing in kind from those normally found. There is, however, one constant change noted by nearly every observer. The bloodvessels are more numerous, and are enlarged, the increase being in the tunica adventitia, and consisting in proliferation of round lymphoid cells. This has been noted by Rasmussen,[19] Wilkes, and Moxon,[20] Crocker,[21] and (according to Rasmussen) by Brücke, Leydig, Robin, and His. Fenger,[22] in a recent case, notes this same peculiarity.

Strange to say, comparatively few observers note any changes in the lymphatic vessels. In view of the generally accepted pathology of elephantiasis, this omission seems strange. Even should lymphatic involvement be an essential part of this disease, it would not change its character as a mesoblastic process, as the lymphatic vessels are derived from that layer.

Summing up, elephantiasis may be defined to be a disease characterized by an enormous connective-tissue hypertrophy, accompanied by an increase in the number of bloodvessels, with thickening of their walls and proliferation of lymphoid cells in their tunicæ adventitiæ, and also, in some cases, by an alteration in the size of the lymphatics.

By every observer, in a position to judge, the tendency to keloid has been recognized as a peculiar characteristic of the dark-skinned races. To such an extent is this true that it has grown into a fixed tradition that any injury in a colored person, especially a full-blooded negro, will be followed by the development of this fibrous growth. Every American observer has noted this racial peculiarity, and the same is true of not a few foreigners whose opportunities have been good.

As to the frequency of keloid among whites, Professor James C. White[23] gives an interesting analysis of the comparative frequency of certain skin-diseases in America, as compared with Scotland, Ireland, England, and Austria (Vienna). The cases are divided into two classes, dispensary and private cases. With reference to keloid, he reports fifteen cases in 10,000 American dispensary cases; no case in 3000 similar Irish cases, and but one in 23,944 cases reported from the great Vienna clinic. The statistics from private cases are not less interesting. In 2000 American cases of this class there was but one case of keloid. No case of keloid was reported in 1000 Scotch and 10,000 English cases of this character. Of course in these statistics there is no attempt to classify as to color.

Since 1878, the American Dermatological Association has published yearly reports of the number and character of skin-diseases coming under the observation of its members. The report for 1890 brings the total number of cases observed since 1878 up to 157,067. Of this number, 179 were cases of keloid, a percentage of 0.114. While the element of color is excluded from these statistics, it is interesting to note that many more cases of keloid are reported from cities having a large population of colored people than from those less favored in this respect. Morison,[24] in a careful study of 1000 cases of diseases of the skin, 500 in white and 500 in colored persons, gives some valuable information. For the sake of greater accuracy he divides the colored into pure blacks and those of mixed blood. As to keloid, he notes no cases among the whites, none in the mulattoes, and three in the pure blacks.

Since June, 1891, I have examined 152 colored persons with reference to this growth, and I have found keloid in 9 instances. During the interval I have examined 392 whites and found no cases of keloid. Of course, had the examination been confined to skin-diseases alone the percentage would have been larger. The statistical tables of the Johns Hopkins Hospital for the year ending January 31, 1891, show 1 case of keloid among 526 whites, and 2 cases among 92 colored patients in the surgical wards. Every American author on diseases of the skin notes this proneness of the colored race to keloid. Among others, mention may be made of Duhring,[25] Hyde,[26] Atkinson,[27] and Morison.[28]

At the meeting of the American Surgical Society, in 1888, Tiffany[29] read a paper on "Surgical Diseases in the White and Colored Races," basing his conclusions on 4390 cases, 64 per cent. being white and 36 per cent. colored. Among other things, he states that keloid is very common among negroes and rare among whites. In this conclusion he was sustained by such excellent observers as Briggs, Gregory, and the late Christopher Johnston, the last-named going so far as to say that he regarded the occurrence of keloid as characteristically frequent in the negro, and, of course, in a figure greatly preponderating over that among the white race. This racial tendency has not escaped English observers. The careful report of the "Keloid Committee" of the Clinical Society[30] mentions as a well-known fact the frequency of this growth in the negro after blows and cuts.

Lastly, I desire to summon as a witness Dr. Rufz,[31] the French physician before alluded to. In an analysis of the cases of skin-disease seen by him during his twenty years' residence in Martinique, he divides them into:

1. Those never seen.
2. Those rarely seen.
3. Those most frequent.
4. Those that appear peculiar to Martinique.

In the last class is keloid, which he describes in the following language:

"Voici une affection de la peau qui me paraît particulière à la race noire. . . Au premier coup d'œil, elle peut être confondue avec l'éléphantiasis des Arabes et a peu passer pour être une de ses variétés. . . Ces saillies sont très fréquent chez les noirs, j'en ai vu quelques exemples chez les mulâtres, mais jamais je n'ai vu rien de semblable chez le blanc."

I think the evidence will warrant the conclusion that we have in keloid a disease affecting in a peculiar degree the dark-skinned races. Perchance it may seem an omission that no attempt has been made to separate the true from the so-called false keloid. Histologically there is no difference, and some good observers go so far as to deny the possibility of spontaneous keloid, claiming that in every case of this disease there must have been a preceding injury, although this may have been so slight as to have escaped notice. It is true that some pathologists claim that in spontaneous keloid the rete and papillæ are present, while in the cicatricial variety the entire structure of the skin is replaced by new connective-tissue growth. The distinction seem factitious and not to rest upon a sufficiently solid basis to warrant its acceptance.

Pathologically, keloid is a pure connective-tissue new-growth, beginning around the bloodvessels. It is intermediate in character between a cicatrix and sarcoma. In its minute anatomy it consists of parallel connective-tissue bundles, running in the corium. In the more advanced cases the connective tissue replaces the entire structure of the corium. The walls of the bloodvessels are infiltrated, and this infiltration extends for a long distance beyond the borders of the growth. This change in the adventitia is especially marked at the edges of the growth and at the parts where the arteries send branches into the papillæ.

Comparing this with the pathology of elephantiasis a great similarity may be noticed. There is in both a true connective-tissue hypertrophy, an absence of any element differing in kind from the normal structure, and a development by cell-proliferation, beginning in the walls of the smaller bloodvessels. The two are nearly alike, but in keloid the epidermis being, as a rule, destroyed, there is a tendency to growth outward, above the level of the skin, while in elephantiasis the cuticle always forms the outer layer of the thickened mass.

Coming now to the third fibroid process peculiar to the dark races, we must, for the most part, accept the testimony of American observers, for the reason that they alone have had the requisite opportunities to judge as to the relative frequency of these growths in the two races. The language of Peaslee[32] is most emphatic. After stating that the uterine fibroid is very common in the negro race, he goes on to say that "very few women die, above the age of forty, at the Home for Colored Women in this city (New York), who are free from this disease." Briggs, of Nashville, at the meeting of the American Surgical Society in 1888, referring to the diseases of the negro, noted that abdominal fibroids are very common, and that the greater number of abdominal tumors in the negro belong to the fibroid or fibro-cellular variety. Tiffany,[33] Ware,[34] William H. Flint,[35] Thomas,[36] and many others, confirm this testimony. J. B. S. Jackson,[37] speaking of the diseases of Barbadoes, remarks that there seems to be as much as most persons would desire to see in the form of polypi and fibroid tumors. In the Johns Hopkins Hospital,[38] during the year ending January 31, 1891, there were treated in the gynecologic service, 373 white, and 89 colored persons. Of the former, 11, or 29 per cent., suffered from uterine myomata, and of the latter, 8, or 9 per cent. were afflicted with these growths. My friend Dr. D. S. Lamb, of this city, has kindly allowed me access to his record of autopsies. Of these, 85 were made on females over the age of fifteen years, 20 being white and 65 colored. In the whites uterine fibroids were only once found, or in 5 per cent. of bodies examined. They were present in the colored in 10 out of 65, or 15 per cent. In the report of the Government Hospital for the Insane for the year 1892, the pathologist of the institution, Dr. I. W. Blackburn, a most competent observer, gives synopses of post-mortem examinations in 69 cases of mental disease in females, with special reference to the condition of the organs of generation. Of the 69 cases 34 were white and 35 colored. Leiomyomata of the uterus, often multiple, were found in 17 cases, 15 of which were colored.

Dr. Rufz,[39] to whose careful observations I have already expressed my indebtedness, bears testimony in this particular equally as strong as in the cases of elephantiasis and keloid. He says:

"La fréquence du polype utérin à la Martinique m'a fait penser quil y avait dans le sang du négre quelque élément propre à la production des corps fibreux, ainsi que semblerait aussi le faire croire cet autre fait de la facilité des hypertrophies fibreuses de la peau à la suite des blessures et les heurts les plus legers."

The supposition hazarded by this shrewd observer that there is something in the blood of the negro predisposing to the development of fibrous growths is entirely in the line of my own thought and argument.

Personally, I have not had sufficient experience in this class of tumors to warrant any definite statement as to their frequency. A glance at the pathology of these growths will, I believe, show a structure somewhat similar to that of the two before considered. To begin with, they are mesoblastic growths. They are strictly homologous to the uterus in structure, and consequently contain a varying amount of muscular tissue. Consisting, in the beginning, almost entirely of unstriped muscle, they rapidly undergo fibroid degeneration—so rapidly, in fact, as to lead almost irresistibly to the conclusion that the change is fibroid from the start. The tendency among pathologists, in late years, has been to consider these growths as myomata, but the period of pure myomatous structure is short, if indeed it exist at all. They soon become fibroid, and, like all fibroid structures, are prone to undergo calcareous degeneration late in their history. Again, it must be borne in mind, as Sutton pertinently remarks, that all fibrous neoplasms may not have been composed of fibrous tissue originally, but may have consisted in great part of unstriped muscle-fiber which has later degenerated into fibrous tissue. This may be the true key to the underlying changes in elephantiasis and keloid.

As keloid and elephantiasis contain the elements of the corium, so these growths contain the elements of the uterus, but the growth is none the less a connective-tissue one. The more the muscular structure predominates, the more firmly is the tumor connected with the uterine walls. These growths are encapsulated, and between the capsule and the main body of the growth is a layer of loose connective tissue, in which run many bloodvessels, often of large size.

Kleinwächter[40] describes the evolution of these tumors from certain round cells which occur alongside of slowly-obliterating capillaries. These round cells are later transformed into spindle-shaped corpuscles which arrange themselves in such a way as to form myomatous nodules. This pathology is not dissimilar to that of elephantiasis and keloid.

There is the same lack of foreign elements, and the same increase of fibrous tissue from cells deposited around the capillary bloodvessels.

Reasoning by analogy, we should expect to find fibroma less frequent in the white than in the dark-skinned races. It is doubtful, however, whether tumors of this class are sufficiently numerous to warrant a classification in this respect. If ever such a classification be made, I believe the law will be found to hold good.

It is possible that the ease with which fibrous tissue is formed in the colored race will explain, in part, the rapid healing of wounds in them. The process of healing in wounds is, in its essence, a connective-tissue process, and in accordance with the facts already laid down, it would naturally be expected that it should take place more readily in the dark-skinned races.

Sarcoma is the most frequent of the malignant neoplasms in the colored race. This is my own observation, and that of all other observers who have had much to do with these people. Tiffany,[41] Briggs, and others, make this statement. This is only what might be expected, if fibroid processes are a characteristic of the race. Sarcoma is the purest type of a connective-tissue neoplasm, containing, as it does, only the elements of the embryonic connective tissue, and it would be only natural that it should be the form of malignant neoplasm most frequent in the colored race, if our contention as to the liability of this race to fibroid processes be true.

I think that sufficient proof has been adduced to show that we have, in the frequency of these fibroid processes in dark races, a distinct racial peculiarity.

If the premises here laid down be correct, the following conclusions may legitimately be drawn:

First. The dark-skinned races differ from the white race anatomically, physiologically, and pathologically.

Second. That there are three diseases characteristically frequent in the dark-skinned races, as shown by the independent testimony of English, French, and American observers. These are elephantiasis Arabum, keloid, and the so-called uterine myomata.

Third. That these are all mesoblastic growths, and that in general terms their essential characteristic may be said to be an increased development of fibrous tissue, due to proliferation of cells around the capillaries, these being increased in number and size, and having thickened tunicæ adventitiæ. They are true inflammatory scleroses.

Fourth. That in respect to malignant growths, the same connective-tissue type predominates.

Fifth. That it may be laid down as a pathologic law, not heretofore enunciated, that there is some peculiarity in the dark-skinned races rendering them liable to growths of a fibrous nature in a degree greatly exceeding that observed in the white race.

CONCERNING THE ETIOLOGY OF ECZEMA.[1]

BY A. RAVOGLI, M.D.,
OF CINCINNATI, OHIO.

HEBRA'S comparison of eczema to the irritation of the skin produced by croton oil, with due deference to this distinguished teacher, I believe to be incorrect. Like any other irritant, croton oil produces an inflammatory condition of the skin known as dermatitis. Dermatitis must be clearly distinguished from eczema, though many forms of acute eczema are really cases of dermatitis. The point that I would emphasize is that dermatitis is not

[1] Read before the Pan-American Medical Congress, held at Washington, D. C., September, 1893.

eczema, although dermatitis may produce eczema. Both affections are based upon an inflammatory process.

Let us investigate the clinical difference between these conditions. Inflammatory processes of the skin, like those of any other organ, consist in vascular changes, hyperemia, exudation, nutritive disturbance, alteration of the peripheral sensory and motor nervous apparatus, pain, and disturbance of function. Every pathologic process showing these characteristics is without doubt inflammatory, as are also in eczema the changes in the nutrition of the tissues and the disorders of the peripheral sensory nerves, although not so intense. When we find an active hyperemia accompanied by an effusion of serum and emigration of blood-corpuscles, we do not hesitate to consider the condition an inflammatory process, as it falls under the description of Celsus: *Calor, rubor, tumor, dolor.*

It is true that Auspitz[1] proposed to call any one of the inflammations of the skin, whether superficial or deep, a dermatitis. While Hebra reserved the term dermatitis exclusively for the deeper-seated inflammations of the skin, we cannot deny that eczema is an inflammatory affection of the skin, hence a dermatitis; but everyone who has had experience with diseases of the skin, finds that it is an inflammatory process *sui generis*. We speak of eczema erythematosum, papulosum, rubrum, impetiginosum, or squamosum as simple varieties of eczema in degree, but not varieties in kind or cause.

Török describes eczema as an inflammatory alteration of the epidermis, accompanied with infiltration of serum and of small cells. Chronicity is the characteristic of eczema, and this characteristic, according to Török, finds its explanation in the continued tendency to relapse, either at the point of origin or in surrounding regions. So we conclude that there is no true acute eczema, but that the so-called acute eczema is only relative. The severity of the symptoms depends on the reaction of the skin of different individuals to irritations. For instance, the heat of the sun will in one produce a dermatitis which does not exceed the degree of an erythema, while in another it will produce vesicles and an abundant exudation, constituting what has been called acute eczema, or better, *dermatitis calorica*. But these symptoms do not constitute a true eczema, though under favorable circumstances a dermatitis may be followed by eczema. I have often seen in my clinic well-nourished children of healthy parents with eczema around the nose, the chin, and in scattered patches on the cheeks. Abundant muco-purulent discharge oozes from the nose. In these cases the eczema doubtless results from the continued contact of the purulent matter with the skin. Cases of eczema auriculæ, spreading down the maxillary and cervical region, with the formation of vesicles, pustules, covered with thick crusts, are frequently brought to my clinic. The ear is affected with otitis media purulenta, pus of offensive odor being discharged from the meatus; here too there is no doubt that the cause of the eczema is to be ascribed to the presence of the pus. I have often seen cases of eczema in the form of scattered pustules under poultices applied to suppurating surfaces, and which have remained for a long time in contact with the skin.

I would illustrate these points by the following case:

Case I.—Miss S. S., a professional nurse in a hospital, had several patients with purulent discharge from the vagina. Twice daily she used to syringe her patients, introducing the syringe with two fingers of the left hand. The purulent discharge often went between her fingers. She applied to me to be treated for eczema interdigitalis. She had plaques of eczematous eruption between the third, the fourth, and the fifth fingers of the left hand, from the second to the first phalanges, in the interdigital spaces, in the form of red inflamed plaques, consisting of small vesicles deprived of their epithelium, showing a raw, oozing surface, with an itching and burning sensation. Can we deny that the presence of the pus was the cause of this eczema?

Case II was a barber who shaved some of his customers affected with acne. He spread the soap with the dorsal surface of his right hand, and pustules appeared at this point. He called on me with eczema on the whole dorsal surface of the right hand, showing plaques of vesicles in different stages, some broken, covered with crusts, some filled with sero-purulent fluid, on an infiltrated basis, with innumerable rhagades toward the joints. The man, in perfect health, never had any other trouble with his skin, and no other cause could be found than that pus had remained on his hands, rendered already tender from the continuous use of water and soap.

These examples can be multiplied indefinitely, and I must say that from their consideration I have reached the conclusion that the presence of pus on the skin is one of the most effective causes of eczema. This conclusion receives support from the communication of H. Leloir,[1] who holds that impetigo is a contagious disease. He refers to cases of pustules and ecthyma, which were communicated from the mother to the child, and *vice versa*. He reports the case of a man affected with impetigo of the beard, who by scratching transmitted the cocci of

[1] System der Krankheiten. Wien, 1881

[1] Journal des Maladies Cutanées et Syph., 1891: "Ueber die nach Impfung mit eitererregenden Mitteln entstehenden Hautkrankheiten."

the pus to other parts of his body, showing abundant pustular eruptions in the axillæ.

In scabies the pustules, impetigo, furuncles, are nothing else but the spreading of purulent matter all over the body from scratching. Leloir comes to the conclusion that the cocci of the pus affect every layer of the skin from the epidermis to the deepest layer, causing inflammation, and that they find their way into the skin by any excoriation produced either by parasites or by any mechanical irritation. Leloir, in his cultures, found the staphylococcus pyogenes aureus in furuncles and carbuncles, and in many cases of ecthyma, and which in some cases was mixed with the staphylococcus pyogenes albus. Now, if these cocci from pus are capable of producing inflammation of every organ of the skin, why cannot they produce an inflammation of the epidermis, which we call eczema?

To substantiate this view, I found it necessary to resort to experiment, which I made with the staphylococcus pyogenes albus. I must tender my thanks to Dr. Kramer, Professor of Bacteriology in the Cincinnati College of Medicine and Surgery, who kindly supplied me with a pure culture of the staphylococcus pyogenes albus. In a rabbit the hair of the external portion of the ears was shaved off, and the ear then carefully washed, and rubbed with a pure culture of the staphylococcus. No alteration of the skin could be perceived. Another rabbit was prepared in the same way, and both ears were painted several times with croton oil. After twenty-four hours both ears were red, painful, and covered with vesicles. The left ear was inoculated with the pure culture of the staphylococcus; the other was left intact. Both ears, after four or five days, presented the symptoms of dermatitis much diminished, the redness lessened, though the epidermis remained hard, dry, and scaly. Ten days afterward, however, the left ear, which had been inoculated with the pure culture of the staphylococcus albus, began to show symptoms of eczema. Small pustules formed, covered with yellow crusts, which when removed showed the rete mucosum, oozing a serous fluid, and—a remarkable fact—the hairs were falling off, producing alopecia. The other ear (the right), which had not been inoculated, but only had been painted with croton oil, was improving, the hardened epidermis was scaling away, leaving a normal surface, the hair remaining intact, except where the ears came in contact with each other. This eczema lasted over four weeks, after which time the crusts began to fall off and the skin to return to its normal condition.

From these experiments I feel justified in assuming the staphylococcus pyogenes albus as a cause of eczema, and that its development under the epidermic cells produces this disease. The staphylococcus does not always find a fertile soil for its development, as it requires that the epidermic cells be loosened that it may penetrate beneath the surface. Inflammation of the skin, dermatitis, is therefore the most effective factor for the preparation of the soil for the penetration of this micro-organism.

My simple experiment shows that the staphylococcus does not develop in healthy epidermis. It is necessary therefore that the ground be prepared for it. This may be the explanation why eczema has been held non-contagious; but if the ground is prepared, eczema is certainly contagious. Everyone can remember cases of eczema of the scrotum in which the eczematous eruption has affected the skin of the thigh in close contact with the scrotum. Very often we see eczema of one leg affect the other, for the only reason that the affected surface is kept in contact with the other, especially while sleeping. Scratching scatters the staphylococci about the skin and prepares the epidermis for their culture. By means of the finger-nails the patient takes the crusts, the serum, the purulent matter, and brings them to other parts of the body, where, finding the epidermis scratched and its horny cells loosened, they begin their work of reproduction. It is no serious objection to my statement that the husband, when affected with eczema, does not communicate the disease to his wife, for one must consider that, first of all, skin-diseases produce a certain natural repulsiveness, and therefore lessen the frequency or closeness of contact. The same precautions are used with other members of the family. Moreover, the healthy epidermis does not permit the development of the cocci, which may only occur with solution of continuity. I can recall plaques of eczema on the breasts of mothers nursing a child affected with eczema of the face.

The contagiousness of eczema is entirely dependent upon the condition of the epidermis, which allows the development of the cocci only when not in an exactly normal condition. My experiment plainly shows this: When I rubbed the ears of the rabbit with the culture of the staphylococcus, the result was negative; but when I rubbed the culture of the staphylococcus after the epidermis had been blistered with croton oil, the skin was affected with an eczematous eruption that lasted over four weeks. In many cases of eczema we can distinctly see the precedence of the irritation and dermatitis, and from them the pus has been formed, which has produced the eczema. Take, for instance, eczema infantile which follows seborrhœa capillitii; the sebaceous masses are formed on the scalp, the glands are inflamed, and under the masses of sebum pus is formed. As soon as pus is formed eczema begins. From its origin we may call this variety eczema sebaceum, in order not to confound it with seborrhoic eczema, which I consider totally different from true eczema. As long as the sebaceous masses do not produce inflammation of the epidermis, the affection remains limited to simple cases of sebor-

rhea; but when the sebaceous masses macerate the epidermis, and produce inflammation, with the formation of pus, the eczematous condition has begun and we have present a true eczema. The child, annoyed by the itching sensation, rubs as much as possible, spreads the purulent secretion on the face and the ears, and thus the eczema extends.

In my experiments I could see that from the time of the inoculation of the staphylococci and the appearance of eczema there is a period of incubation of from one to three weeks. I believe that this period of incubation can be called upon to remove the objection that sometimes an eczema has recovered, and that a short time after it reappears. We should remember that sometimes the cocci remain between the connections of the epidermic cells, and that with the naked eye or with a common magnifying glass nothing can be perceived. This may explain why in one or two weeks eczema appears again as a "relapse." These kinds of eczema are often considered as nervous eczema on account of the tendency to relapse.

The skin differs in susceptibility to eczema, some individuals affected with scrofula being much more liable to it than others. Eczema is not transmitted by heredity, but there may be transmitted the vulnerable skin, which may predispose to the development of the disease. Nothing is transmitted in eczema; no *materia peccans* is transmitted from parent to offspring, but only a weak constitution or an easily-affected skin makes the offspring subject to eczema.

Neither do I agree with my distinguished colleague, Dr. D. L. Bulkley,[1] who attaches so much importance to the nervous system in the production of eczema. In a large number of patients suffering with this disease in every shape and form—circumscribed, universal, papulosum, rubrum, squamosum, etc.—I can say that in nearly every one I could not find any nervous trouble. The only thing which is often remarkable is sleeplessness, the result usually of the itching sensation which nearly always attends eczema.

I do not wish to dispute this point, as not more than one year ago I admitted the presence of a nervous eczema produced by reflex action of the nervous system. I do not doubt the truthfulness of the cases referred to by Meyer[2], Leloir, Tommasoli, Radaven, and many others, but what I want to ask is this: Were all these cases of true eczema? As I said, I have seen cases of acute eczema follow dietetic disorders, such as excessive smoking, but, although one year ago I was inclined to call those cases acute eczema, to-day I am willing to call them dermatitis, with a qualifying adjective such as neuritica, vesiculosa, etc.; but I am no longer willing to let them pass under the name of eczema. My rabbits, when they got eczema, had no moral shock, but on an inflamed surface of the skin they had inoculated the culture of the staphylococcus albus. In the same way, if all these cases have eczema they took it from the pus on an inflamed skin. I am fully convinced, with Bulkley, that children at the time of dentition may have a vesicular eruption of the face; I am not opposed to the belief of Scarenzio, that his patient had a vesicular eruption on account of the presence of a tapeworm in the intestines; I do not deny the presence of a vesicular eruption in women at the time of pregnancy, or of the catamenia—but are these eruptions true eczema? I answer, *no*. They are only cases of dermatitis, neuritic eruptions, herpes, entirely different from true eczema. That eczema could follow these eruptions there is no doubt, when we remember that a sero-purulent discharge was furnished by the vesicles, or by the bullæ, and the presence of the staphylococci on the skin could at this time produce eczema. By scraping with a sharp spoon upon the eczematous surface and staining the scraping with methyl-blue we obtain isolated epidermic cells that show a large quantity of staphylococci. Staphylococci in their development produce toxins, to which the tissues cannot remain entirely indifferent, and also toxalbumins. The toxalbumins, to produce their effect, need to find an excoriation or an abrasion, otherwise they remains harmless.

Bockart, in 1887, had already produced pustules by the artificial inoculation of the staphylococcus pyogenes albus, and flavus, and this furnishes another support to my theory. From Konrad and Buedinger[1] we know that as soon as the staphylococci of pus appear in a wound, the healing *per primam intentionem* is disturbed. Staphylococci applied on the skin of the arms of the authors caused follicular abscesses, with this difference, that staphylococcus albus and aureus produced mild irritation, while the staphylococcus citreus produced severe suppuration and deep furuncles. From the different cocci, different forms of eczema arise, a difference which may also depend upon the different organs of the skin affected. Although my work is not complete, it seems to me to justify the following conclusions:

1. Eczema is a local affection of the epidermis of a chronic inflammatory character, contagious under favorable circumstances.

2. It is caused by pyogenic microörganisms (staphylococcus pyogenes albus) developed upon a previous inflammation of the skin.

HALLUX VALGUS.[1]

BY JOHN B. DEAVER, M.D.,
OF PHILADELPHIA;
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC; ASSISTANT PROFESSOR OF SURGICAL ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA.

IN reporting this case of double hallux valgus, in which the deformity has been corrected by subcutaneous osteotomy of the neck of the first metatarsal bones, I propose to call attention as well to the varieties of this deformity, whether existing alone or in connection with enlargement of a mucous bursa developed in the superficial fascia covering the prominent portion of the head of the metatarsal bone, the result of prolonged pressure (bunion), and to the different forms of treatment.

The varieties of hallus valgus may vary from a slight abduction or displacement outward of the great toe, to a position in which the proximal phalanx is almost at right angles to the metatarsal bone. In the latter variety of the deformity the great toe lies either underneath or on top of the adjoining toes. In the aggravated varieties of this affection the deformity is not bony alone, but there is also a swelling over the site of the metatarso-phalangeal joint due to bursal enlargement. The several conditions that may constitute factors in the production of hallux valgus are the following: That which is the most common in my experience is crowding the feet into too narrow and too short high-heeled shoes. This is unfortunately the popularly shaped shoe. Short and narrow shoes contribute to this deformity by forcing back the last phalanx when the contact with the shoe prevents elevation and consequent flexion of the joint between the proximal and the second phalanx. On account of the resistance offered by the shoe, coupled with the lateral mobility of the first metatarso-phalangeal articulation, the toe is carried outward, or abducted. When any of the remaining toes are subjected to a like pressure on account of the absence of resistance on the part of the shoe, the proximal phalanx is lifted and the first phalangeal joint is strongly flexed, giving rise to what is known as "hammer-toe."

If the foot is forced into a narrow and pointed shoe the points whereon the greatest pressure is produced are the heads of the metatarsal bones of the great and little toes, resulting in the formation of a corn over the metatarso-phalangeal joint of the little toe, while the great toe, on account of its greater lateral mobility, becomes abducted, owing to the pressure on its extremity. This displacement of the great toe forms, to a greater or less extent, an incomplete luxation of the proximal phalanx. The exposed portion of the articular surface of the head of the metatarsal bone, being now no longer in contact with the articular surface of the phalanx, is subjected to continuous pressure, and becomes enlarged from proliferation of bony tissue. If the head of the metatarsal bone is not relieved of the pressure of the boot there will be produced a bursa over the enlarged bone, which not infrequently suppurates, leading to a most painful condition. Bursal fistulæ, consequent upon ulceration of the bursa, are often seen. These, too, may involve the joint, causing inflammation and suppuration. Again, it not infrequently happens that the synovial lining of the entire joint and also the articular cartilages, undergo change, resulting in an arthritis of a mild or severe degree.

Contraction of the muscles of the great toe, the result of infiltration dependent upon a rheumatic inflammation or of inflammation of the nerves supplying the muscles, may be enumerated as one of the causes of this deformity, yet it must be a very remote one. Another cause may be chronic inflammation of the joint, of the metatarsal bone, or of its periosteal covering, due to traumatism. I believe, however, as I have previously stated, that pressure, either alone or combined with other causative factors, is the chief element in the production of the deformity.

The treatment of hallux valgus will depend entirely upon the degree of the deformity, the amount of discomfort, etc. If seen very early, and the deformity be but slight, it may suffice simply to have the patient wear a properly fitting shoe, by which I mean one with comparatively wide toe and a very low heel, thus avoiding crowding of the toes. A properly fitting shoe should not in any way tend to diminish the transverse diameter of the foot between the heads of the first and fifth metatarsal bones. The use of plasters for protection applied over the projecting head of the metatarsal bone of the great toe, or over an enlarged bursa, is, I believe, capable of doing more harm than good, and in time, with this treatment, the deformity must surely increase, especially if the shoe worn is not very roomy at the toe. The use of appliances, such as devised by Biggs, I believe is equally ineffective. When the deformity is great enough to indicate the adjustment of an appliance I always feel that operation is more strongly indicated.

The operative treatment should consist either of osteotomy of the neck of the metatarsal bone, or excision of the joint. In my experience osteotomy fulfils the indication best in the great majority of cases. When a large bursa is present I dissect it out before dividing the bone. The degree of deformity, so long as there is no great disorganization of the joint-surface, should not influence the

[1] Read before the Section on Orthopedic Surgery of the College of Physicians of Philadelphia.

operator against osteotomy, as the deformity can be wholly corrected by this procedure.

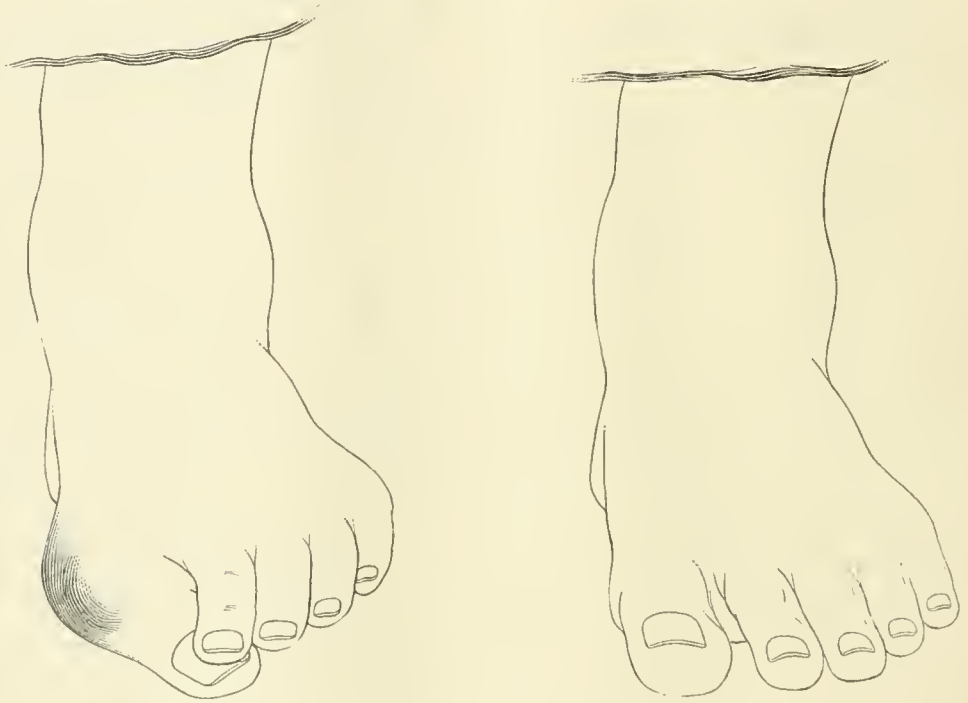
In the class of cases in which the proximal phalanx is displaced outward to the extent of making a right angle with the metatarsal bone, the thickest osteotome should be used, so as to have the incision as nearly V-shaped as possible, thus allowing the toe to be brought in a position of strong adduction.

In performing osteotomy the foot is rendered bloodless by the application of an Esmarch bandage and tube. The incision through the soft parts, including all of the tissues down to the bone, is carried over the neck of the bone along the inner side of the foot. The foot, as in osteotomy of other bones, is made to rest on a small bag of sand.

The bone having been divided, the wound is closed with catgut sutures and dressed with the ordinary antiseptic dressing. The great toe, being strongly adducted, is held in this position by a straight splint with a hole at the base to fit the internal malleolus and applied along the inner side of the foot. At the end of a week or ten days the splint is removed and the foot dressed with plaster. This dressing is allowed to remain in place for six weeks, when it is removed and the patient allowed to use the foot as before.

Excision of the metatarso-phalangeal joint of the affected toe I perform only in that class of cases in which the joint is positively disorganized, as demonstrated by the presence of physical signs of advanced arthritis. In the milder cases of arthritis arising in connection with hallux valgus recovery will surely follow correction of the deformity by oeteotomy. Crepitation, present so frequently in chronic articular disturbances, does not by any means imply a stiff joint when repair shall have become complete.

The more conservative operations that have been advised, such as subcutaneous section of the external lateral ligament of the affected joint, or of the tendons of the adductor or flexor brevis pollicis muscles, I believe, are capable of accomplishing but little in the way of correcting the deformity; I therefore neither practise nor advise them.



The appearance of the foot before and after operation.

Amputation can but seldom be required, as excision in the class of cases in which amputation might seem indicated will, in the majority of instances, be the better operation. The same conditions, however, such as advanced age, the presence of a constitutional diathesis, etc., that, under other circumstances, make amputation preferable to excision, must be carefully considered.

HISTORY OF A CASE OF HALLUX VALGUS.

E. McC., twenty-two years of age, was admitted to the German Hospital with the following history: He had had both toes frostbitten last January, and stated that this accident was the cause of two "bunions" that appeared shortly afterward over the metatarso-phalangeal articulation of either great toe. The man consulted a surgeon, who lanced both "bunions." Since that time the patient has had much

trouble in wearing shoes and great pain in walking. He was admitted to the hospital during the latter part of September, with marked hallux valgus of both feet. A subcutaneous osteotomy was performed upon the metatarsal bone of either great toe, the toe straightened, and a straight splint adjusted to the inner side of either foot. The bandages and splint were removed for the first time four weeks after the operation, when perfect union was found to have taken place. A silicate dressing was then applied and the patient discharged five weeks after the operation. He was readmitted four weeks later with a slight bursitis of the left foot, which yielded rapidly to applications of lead water and laudanum.

ORIGINAL ADDRESS.

THE PHYSICIAN IN LITERATURE.[1]

BY ARTHUR W. HURD, A.M., M.D.,
OF BUFFALO;
LECTURER ON INSANITY.

THIS evening marks the beginning of a new college year, the first complete college year in this, our new building, and I appreciate the honor conferred upon me in being selected to deliver the first opening address.

We should congratulate ourselves in possessing so complete and beautiful an edifice in which to do our work, and we should testify our appreciation of the zeal, the energy, and the self-sacrifice that made this building a reality—that out of a realm of misty possibility brought it into being. For many years it was a wish, a necessity, ardently desired by friends of the college. I think I do no injustice to all those who labored so earnestly for it to say that perhaps our first thanks are due to the energy, the loyalty, and the labor of Dr. Charles Cary.

This building, however, is only a tool, an instrument for a certain purpose; it is a means, not an end; and, as the finer the tool the better the work, so we shall expect students and faculty to accomplish greater results than ever before. I assume that every student enters upon the study of any profession with a certain purpose, and only after a certain deliberation and thought. I believe he should enter upon it only with the highest motives and ideals. If *anyone* should enter a profession with a high standard before him and a pure ideal, it should be he who, in the capacity of the trusted physician, aims to make himself fit to enter all walks of life.

The man who enters any profession without love for it, and simply to make a living, without respect for its honor and high standing, will do his share toward lowering it in public respect, even though he do not intend this. Of him it may be said, as De Tocqueville said of American Democracy: "The man who seeks freedom for anything but freedom's self is made to be a slave." The one who enters upon a course of study for a degree, planning how little he can do in three or four years, rather than how much, is doing himself and the profession an injury.

[1] Address delivered at the opening of the Medical Department of the University of Buffalo, September 25, 1893.

But it is not my intention to moralize, only, if possible, to indictate certain directions, not strictly medical, whereby the members and intending members may discharge a duty to themselves and to the high standing and honor of this profession, which it should be their ambition to sustain.

That every student should make the most of himself, should broaden his culture to the extent of his ability, is an axiom that no one will dispute, and yet, trite as it is, I fear it is not always heeded by the student of medicine. It is my desire to impress the fact that while to know one's business may be the whole duty of the *medical* man, it is *not* the whole duty of the cultivated physician; not the whole duty to himself, or to the standing of his profession before the public.

The very term, *medical man*, in itself illustrates the comparatively low standing of the profession in that mother country of ours, where it is the common term. For our own welfare it behooves us, as students, to prevent any possibility of our descent to the level of a trade, which that term implies.

However, it has not always been so even in England. In the seventeenth century, not only did the classic side of the physician outweigh his scientific attainments, but it secured for him the respect and the high standing so often referred to in the literature of Shakespeare's time. "The wealth and social position of the olden physician," says Dr. Bucknill, "is apparent even from many satirical attacks of the time. Thus, it is shown that they habitually rode in coaches when to do so was the luxury of the rich and great; they clothed in velvet and wore velvet caps of a conceited cut, but above all they aimed at maintaining themselves at the highest level of intellectual aristocracy in their knowledge of the learned and modern languages and other attainments in the general science and literature of their age." Of Dr. Linacre, the founder of the Royal College, it is said that "Returning to England, he brought languages with him, and was the first restorer of learning in our nation." Medicine was of such standing that the greatest dramatist of all literature referred to it constantly in his plays. In fact, Shakespeare undoubtedly derived much of his evident medical knowledge from his son-in-law, a noted physician, Dr. John Hull, who married Susanna Shakespeare.

In the present century this classic learning has given place to a more material scientific standard, absolutely essential in itself, but nevertheless detracting from that broader position. Thanks, however, to the efforts for a higher preliminary and medical education, the pendulum has begun its return-swing again. To assist this movement is the aim of this college; to assist it is in the power of its every student and alumnus; and that it is for our pleasure and our advancement to assist it, it is my desire to show.

But let not the thought be lost sight of that the duty of the student is, first and foremost, to perfect himself in his knowledge of medicine. No success, no distinction, no fame in arts or letters, or in other fields, can atone for neglect of this. This is the foundation on which his other attainments may be added, but may not supplant.

The cultivation of letters, the pursuit of literature, achievements in the sciences allied to medicine—these

not only add directly to the reputation and the influence of the physician who broadens thus his scope, but they add directly to the sum-total of the knowledge of the world. And further still, they stimulate the mental vigor of the intellectual world, and in the gain the physician's own profession reaps its share of benefits as well.

That epochs in medicine have followed revivals of intellectual life has been most aptly shown by one of our own profession who so well illustrates in his own life the high ideal and the broad scope of culture that I have sought to impress—Oliver Wendell Holmes:

"It was in the age of Pericles, of Socrates, of Plato, of Phidias, that Hippocrates gave to medicine the form which it retained for twenty centuries. With the world-conquering Alexander, the world-embracing Aristotle, appropriating anatomy and physiology among his manifold spoils of study, marched abreast of his royal pupil to wider conquests. Under the same Ptolemies who founded the Alexandrian Library and Museum, the infallible Herophilus made those six hundred dissections of which Tertullian accused him. It is significant that the large-minded Galen should have been the physician and friend of that emperor-philosopher, Marcus Aurelius.

"Look at Vesalius, the contemporary of Luther; who can fail to see one common spirit in the radical ecclesiastic and the reforming court-physician, both breaking through old traditions in the search of truth; one, knife in hand, at the risk of life and reputation; the other at the risk of fire and fagot, with that mightier weapon which all the devils could not silence, though they had been thicker than the tiles upon the house-tops.

"Harvey himself was but the posthumous child of the Elizabethan period. Bacon was at once his teacher and his patient. The founder of the new inductive philosophy had only been dead two years when the treatise on the Circulation—the first fruit of the restoration of science—was given to the world. And is it to be looked at as a mere accidental coincidence that while Napoleon was modernizing the political world, Bichat was revolutionizing the science of life; that while the young general was scaling the Alps, the young surgeon was climbing the steeper summits of unexplored Nature; that in the same year one read those admirable *Researches on Life and Death* and the bulletins of the battle of Marengo? If we come to our own country, who can fail to recognize that Benjamin Rush, the most conspicuous of American physicians, was the intellectual offspring of the movement that produced the Revolution?"

And coming down, I may add, to a later time, we may recognize the same truth exemplified in the progress in medicine and surgery from the tremendous stimulus to mental work and achievement incident to our own Civil War. Material things—commerce, manufactures, productions generally—took on prodigious life and energy. Mental action was also intensely quickened. Men then, by the mighty logic of events, were forced to think and to act, and behold our progress! What was surgery, as we now know the word, before the war; and what has it become, from that very intellectual quickening! The same experience has been had with bacteriology, and every branch of the science.

Progress in medicine, as in every other department of intellectual life, thrills with the enthusiasm of a quickened national mental vigor, or droops with its decline, and he swells his own intellectual wealth who adds to the mental capital of his country and of his time. As true also is it that he who countenances false beliefs, who leads the world into error, medical or other, issues a counterfeit coin, difficult to recall and morally debasing.

It is not all of life to live, nor is it all of a physician to know the art of healing. The responsibilities he has to bear, the counsel he is to give, the confidence he should deserve—all call for the broadest culture and the deepest humanity of which he is capable.

Let the student therefore cultivate some other field—the study of ornithology, if he will—and become an Elliot F. Coues or a Shufeldt, and bring honor to himself, his profession, and his country. Or let him cultivate the science of vital statistics and medical and surgical history, and become a Billings, to place his country and his profession in the front rank in this department of all the countries in the world. Or let him cultivate the science of government and political economy, and, while not detracting from his medical powers, emulate a Virchow, whose name and fame, and whose profession are, because of him, honored in the medical and political life, not of Germany only, but of the world. Or, like a certain distinguished student of anatomy, he may turn his attention to the natural sciences and win fame for self, and make the world his everlasting debtor—an Alexander von Humboldt. Or he may turn from scenes of sickness and suffering and depict the scenes of Nature in her happier moods, and with the etcher's tool work out for himself rest, recreation, and fame, and for the world, ennobling pleasure, and still be the surgeon and artist—a Seymour Hayden.

Should any urge that medicine is too broad a science to allow time for other pursuits, too jealous a mistress to permit attention to her rivals; that her study unfits one for the pursuit of other branches, I might reply that work and mental discipline increase the power for work; that he has time for work who has no time, and that he who has abundance of leisure is the man who has no time to produce anything of value. I might reply with the words of that artist-philosopher, Philip Gilbert Hamerton, who says:

"The profession is, of all fairly lucrative professions, the one best suited to the development of the intellectual life. Having to deal continually with science, being constantly engaged in following and observing the operation of natural laws, it produces a sense of the working of those laws which prepares the mind for bold and original speculation, and a reliance upon their unfailing regularity, which gives it great firmness and assurance. A medical education is the best possible preparation for philosophical pursuits, because it gives them a solid basis in the ascertainable. The estimation in which these studies are held is an accurate meter of the intellectual advancement of a community. Where the priest is reverenced as being above ordinary humanity, and the physician slightly esteemed, the condition of society is sure to be that of comparative ignorance and barbarism; and it is one of several signs which indicate barbarian feeling in our own aristocracy that it has a contempt for the study of medicine. The progress of society toward enlightenment is marked by the steady social rise of the surgeon and the physician, a rise that still continues in Western Europe. It is probable that before very long the medical profession will exercise a

powerful influence upon general education and take an active share in it. There are strong reasons for the opinion that school-masters educated in medicine would be particularly well qualified to train both body and mind for a vigorous and active manhood. An immense advantage, even from the intellectual point of view, in the pursuit of medicine and surgery is that they supply a discipline in mental heroism. Other professions do this also, but not to the same degree. The combination of a training in positive science with the habitual contempt of danger and contemplation of suffering and death, is the finest possible preparation for noble studies and arduous discoveries."

As we read these words of an unprejudiced observer, do they not call up before us those intellectual heroes in medicine, heroes because it took courage and broad-mindedness and culture to face an almost universal opposition! Does it not call up Vesalius, and Harvey, and Hunter, and Paré, and scores of others whose culture and whose courage have made the world progress, in spite not only of scorn and contempt, but even of disgrace and death!

And there remains yet another field, which in the cultivation yields stores of pleasure and of fame. It is the field of Shakespeare, of Milton, and of Dante. It is the field that never fails its bounteous return, no matter how often gleaned, a help to the weak, a delight to the strong, and a solace to the weary.

In this pursuit of literature may we perhaps find that breadth of culture and that loftiness of ideal which should be the physician's aim. What medical men have done in literature, what pleasure, and what profit, too, they have given to the world, would require a volume to recount; and who can measure to what extent their own labors have been thereby lightened and their profession honored.

To recall a few of the physicians who live in English literature may emphasize to us their work and the impress they have left upon the literary world and their profession. We may remember Arbuthnot, the witty, wise, and good physician to queen and prince, of whom Swift says: "He has more wit than we all have, and more humanity than wit," whose writings, ranging from philosophy to satire, remain his monument.

There should not be forgot the gentle author of *Pleasures of the Imagination*, that high-minded Mark Akenside, who never forgot the duties of his profession, while he won immortality in the pleasures of his pen. Mark Akenside, the man, was but foreshadowed in his youth when he could write his "Hymn to Science" and exclaim:

> "Raise me above the vulgars' breath,
> Pursuit of fortune, fear of death,
> And all in life that's mean;
> Still true to reason be my plan,
> Still let my actions speak the man
> Through every various scene."

And then we remember the author of the *Vicar of Wakefield*, and of *The Deserted Village*, the shiftless, the careless, and the lovable Oliver Goldsmith, a literary and medical tramp, who enriched the intellectual world and rendered English literature his debtor forever—and everybody else his creditor. Indeed, his necessities were at one time so great that he was forced to borrow a new suit of clothes in order to make himself sufficiently presentable before the examining board, at whose hands he sought a governmental medical position. The agreement was that, if successful in the examination, he should thereafter pay for the suit of clothes in instalments as he drew his salary, and in the event of failure he was to return the clothing immediately. He failed both in his examination and in his promise to return the suit, which he disposed of in a pawn-shop. For a time thereafter his life was clouded by visions of a pursuing sheriff. And yet it is with honor only that we remember this unhappy physician, who could write:

> "In every government, though terror reign,
> Though tyrant kings or tyrant laws restrain,
> How small of all that human hearts endure
> That part which laws or kings can cause or cure."

Nor must we forget Erasmus Darwin, who found that his life and standing as an honored and successful physician was in no wise narrowed, but rather broadened, by his love for Nature and her flowers, of which he wrote so well. So, too, of Dr. John Moore, the traveller, the historian, and the novelist, who instructed and pleased his world, who elevated his profession, and who, to alter Shakespeare's words, "Could write and write, and be a doctor still."

Nor could we with justice omit that gentle physician and man of letters who has left much, but nothing so enduring to his fame as *Rab and his Friends*. To him also could I appeal, for did he not urge the broader culture fourscore years ago, when he said: "To give my vote for going back to the old manly, intellectual, and literary culture of the days of Sydenham, Arbuthnot, and Gregory, when a physician fed, enlarged, and quickened his entire nature; when he lived in the world of letters as a freeholder and reverenced the ancients, while at the same time he pushed on among his fellows and lived in the present, believing that his profession and his patients need not suffer, though his leisure hours were devoted occasionally to miscellaneous thinking and reading and to a course of what is elsewhere called 'fine confused feeling,' or though, as his Gaelic historian says of Rob Roy at his bye hours, he be 'a man of incoherent transactions.'

"As I have said, system is not always method, much less progress."

And then there shines as a brilliant example of the broadly-developed man, as the example of most that is best for a man and his profession in true culture, Thomas Huxley. He could be the assistant-surgeon on board her Majesty's ship *Rattlesnake*, and yet be the student of natural sciences who brought home enough material from the South Pacific to build the foundations of a world-wide fame. So, too, we have a John W. Draper, who could be a physician and yet write *The Intellectual Development of Europe*; who could be a teacher of chemistry and write his *History of the Conflict between Religion and Science*, reaching a far wider world and building up a vastly more extended field of reputation and usefulness than would have been embraced by his profession only.

The author of *Peregrine Pickle*, Tobias George Smollett, was a physician as well as novelist, and one of the most indefatigable workers in the field of English literature, which he left enriched. So, too, we might

recall John Armstrong, one of the most happy examples of the literary physician presented to us in the gallery of the eighteenth century, a successful physician and a distinguished poet, and whose profession was the more honored that he had lived.

And then we must not forget the meteoric Keats—the student of medicine and the poet whose brief twenty-five years, cut short by pulmonary tuberculosis, was sufficient for him to win an immortality of fame denied in the proverbial threescore and ten.

Of Crabbe, and Currie, and Charleton, and John Locke, bright examples of a faded generation, we have but time to call their names.

And of those whose fame is peculiarly of our own America must come that honored signer of the Declaration of Independence, who was great enough to be statesman, author, physician, all in one—Benjamin Rush. And still within the Quaker City we find in our own time his fitting successors, distinguished both in medicine and in literature, S. Weir Mitchell, and others.

We come, finally, to the most distinguished living example of the physician and man of letters, the genial Autocrat of the Breakfast Table, who so fitly illustrates that broadness of culture and depth of professional learning are by no means incompatible, and that he honors most his profession who honors all the gifts kind Nature has bestowed. In him are found the subltest wit and highest sentiment. The author of the *Chambered Nautilus* could also write the *One-Hoss Shay*.

With that high ideal of what our art should be, with that conception of what we, its devotees, owe it and owe ourselves, he wrote :

> "Life is but a song, Art is wondrous long,
> Yet to the wise her paths are ever fair,
> And Patience smiles, though Genius may despair;
> Give us but Knowledge, this by slow degrees,
> And blend our toil with moments bright as these;
> Let Friendship's accents cheer our doubtful way
> And Love's pure planet lend its guiding ray,
> Our tardy art shall wear an angel's wings
> And life shall lengthen with the joys it brings."

And so, among his books, and within the circle of that mellowed light, whence dimly peer the spirits of Shakespeare and of Milton, approving both his honor and his usefulness, we may leave the man of culture who has almost solved the secret of a happy life.

ORIGINAL LECTURE.

PISTOL-SHOT WOUND OF THE NECK—GANGRENE OF THE FOOT—VESICAL CALCULUS IN THE FEMALE—TREPHINING FOR EXTRA-DURAL HEMORRHAGE.

A Clinical Lecture, delivered at the Pennsylvania Hospital, October 4, 1893.

By JOHN H. PACKARD, M.D.,
SURGEON TO THE HOSPITAL.

Case I. *Pistol-shot wound of the neck.*—This man, an Italian, of robust frame, thirty-two years of age, was admitted to the hospital late in the evening of September 23d, having been shot in a quarrel. Nothing could be learned as to the size of the weapon or the distance at which it had been fired.

The wound, a very small one, was at the root of the neck, on the left side; it was about an inch and a half from the median line, and about an inch above the clavicle.

Now, in all cases of shot-wound, the first question is: What harm has the bullet done? and the second: What harm is it likely to do?

In this instance the ball entered a region which, as you know, contains large and very important blood-vessels and nerves. Yet on admission the man showed very slight symptoms of shock, his temperature being 98.2°; the wound was not bleeding much, nor was there any evidence that there had been loss of blood to any extent. The pulse was 110, and the respirations 40 in the minute. But with each act of expiration there was a hissing sound of air passing out through the wound, the skin about which was slightly swollen, and crackled when pressed upon with the finger; and there was frequent spitting-up of frothy blood. It was therefore evident that while the great vessels and nerves had escaped injury, an opening had been made in the trachea, permitting the escape of air into the tissues.

At my visit next morning I found the man in fairly good condition, with some considerable extension of the emphysema, but no marked embarrassment in breathing. Under ether, I enlarged the wound somewhat by an incision parallel with the clavicle, and exposed the trachea, at the left side of which there was a small opening cut by the ball as it passed backward and very slightly inward. With a blunt probe I gently followed the course of the bullet for about two inches further, but could feel no foreign body.

Now, as to the second question: What harm was this ball likely to do? It had probably lodged among the mass of muscles at the back of the neck, and the chance was that it would become encysted and lie quiet. I need hardly point out how great an error it would have been either to follow it up by a deep and dangerous dissection from the front, or to make a hap-hazard cut at the nape, in the hope of finding so small a body, which, if let alone, might give no further trouble.

The sinus made by the bullet was sterilized, a strip of iodoform-gauze was loosely placed in it, and an antiseptic dressing applied. Gradually the emphysema subsided as the opening in the trachea closed. The rest of the wound healed quickly from the bottom, until, as you now see, the appearance of the neck is quite normal, but for the scar of my incision and a little button of granulation marking the point of entrance of the bullet.

Case II. *Gangrene of the foot.*—This man, fifty-five years of age, has been sent down to us from the coal regions on account of mortification of his left foot. Until four years ago he was intemperate; he has never, so far as can be ascertained, had syphilis. His present trouble came on without apparent cause about eighteen months ago; it began with sharp, burning pain in the toes. This gradually subsided, and the sensation of the part became lost. About two months afterward the tissues began to dry up and change color. Pain continued to be felt in the body of the foot up to the ankle.

On admission the foot and toes were of a brownish-purple color, hard and dry; on the outer side of the foot, just below the malleolus, there was a large sloughing ulcer. Wherever the pulse could be felt the arteries

were found to be stiffened and resilient from atheroma. Otherwise the man's health was fairly good; there was no evidence of heart-disease. This condition of the vessels, however, always signifies a deterioration of the system. It is one of the features of old age, and is therefore termed a senile change; although, as in this instance, it may occur prematurely. The urine, normal in quantity, was examined and found to be clear, somewhat darker in color than normal, with a specific gravity of 1020; it contained neither albumin nor sugar. Special attention was, of course, given to this inquiry, as gangrene is known to occur as a result of diabetes, and this condition is one unfavorably affecting the prognosis of operations. Albuminuria is generally indicative of chronic inflammatory disorder of the kidneys, and of impaired function of these organs; it is not a bar to operation, but lessens the powers of resistance to shock, and should make one cautious in giving ether.

This dead foot must be removed, as a source not of annoyance merely, but of danger from the absorption of septic material from it into the circulation. And the amputation must be done high up, through healthy tissue, as experience teaches that by so doing we are more nearly sure of avoiding the occurrence of gangrene in the stump. I shall therefore take the limb off just above the knee.

A tourniquet is put on so as to control the circulation through the limb, and now with a large scalpel I mark out a long anterior flap, cutting right down to the bone; this flap, composed of all the soft parts, is turned back, and I pass a long knife behind the bone, and cutting downward and backward make the posterior flap. Running the edge of the scalpel around the bone I divide the periosteum, and turn it back like a cuff for about an inch. This and all the other soft parts are now held back out of the way with a retractor, while the bone is sawn through; the flap of periosteum, as you see, falls down over the sawn end. All the vessels are now tied; the tourniquet being loosened, a few small ones, mainly muscular, are secured. The wound-surfaces are now douched, and the stump is closed by suturing the muscular layers first, and then the skin, with catgut. We try to get exact apposition, leaving no dead spaces or cavities in which wound-secretions might lodge; and as an additional precaution against such retention a piece of rubber drainage-tube is inserted at each angle of the wound. Aristol is dusted all along the line of junction of the flaps, and an antiseptic dressing of sublimated gauze and cotton is applied, with a firm bandage over all. The patient is put in bed, with bottles of hot water around him to promote reaction.

(A few hours after the operation secondary hemorrhage occurred; the stump was opened up, and a vessel or two secured, but there were several renewals of bleeding within the next twenty-four hours. The man began to lose ground; he became delirious, with a high temperature and rapid pulse, and died on the sixth day).

CASE III. *Vesical calculus in the female.*—The next patient is a woman, forty-three years old, also from the coal regions. She was in good health until about five months ago, when she says she caught cold, and had an inflammation of the bladder. Ever since then she has had great pain, shooting from the navel to the pubes; her urine has been scalding, and contained mucus and pus. About a month ago she began to pass blood, and occasionally masses of gravel. For a good while she had frequent calls to urinate, but these have given way to incontinence, her urine flowing away from her continually. Her bowels are much constipated.

Her urine is found to be alkaline, and to contain mucus, with a little blood.

She has been kept at rest since her admission, with a nutritious but non-irritating diet, and a mixture containing benzoic acid, sodium bicarbonate, and a little chloroform. She has been allowed to drink nothing but Buffalo lithia water.

A sound introduced into the bladder comes in contact with a gritty substance, which, if not the whole cause of the irritation, aggravates it, and must be removed.

For this purpose I dilate the urethra by passing into it this pair of dressing-forceps, closed, and then separating the blades. My little finger now goes in readily, and now my forefinger—and a mass of calculous material and thick mucus is at once felt. It is grasped with a pair of stone-forceps and withdrawn. The bladder is now syringed out with hot boric-acid solution, and a suppository of one grain of extract of opium is introduced into the rectum.

In addition to the former treatment, this patient will now take thrice daily a capsule containing ten minims of balsam of copaiba as a sedative to the urinary organs. For some time there will be a loss of control of the bladder, but usually this power is fully regained.

(Immediate and complete relief followed this procedure, and the patient did well; but she left the hospital before the neck of the bladder had recovered its tone.)

CASE IV. *Trephining for extra-dural hemorrhage.*—This man, who is twenty seven years old, was admitted eight days ago, having been thrown from his wagon, and alighting upon his head. He made little or no complaint, but seemed dull and stupid. On shaving the scalp (and this should always be done for the purpose of examination when there is any reason to suspect fracture of the skull) it was found that he had over the right parietal bone, about an inch from the median line, an area of red points of extravasated blood; and here there was a slight bogginess of the skin, with some tenderness on pressure. Believing that the bone had suffered I thought it right to perform an exploratory operation, accordingly I had him etherized, and turned up a flap of the scalp, exposing a fissured fracture of an irregular T-shape. Applying the crown of a trephine, and taking away a button of bone, I came upon a mass of blood-clot lying upon the dura. The opening being freely enlarged by means of Hopkins' rongeur forceps, a large quantity of clot, certainly more than an ounce, was scooped out; there was still some oozing, in spite of the application of hot water. As the coagulated blood was taken away, the brain, covered by the dura, was relieved of pressure and swelled up into its place, pulsating normally. A tampon of iodoform-gauze was laid in the wound, which was brought together somewhat loosely by two or three sutures, and an antiseptic dressing applied. If the wound had been very tightly stitched up, and the oozing had continued, another mass of blood-clot would have formed, and would perhaps have given trouble; but a free exit was provided for the small amount which actually did come away. There were no subsequent symptoms to note.

You see to-day that the wound has entirely healed, and the man is practically well. Had I waited for the signs of compression of the brain to manifest themselves, as they most surely would have done, my interference would have come too late.

CLINICAL MEMORANDA.

TWO CASES OF TRAUMATIC INTESTINAL PERFORATION, WITH RECOVERY.

By H. M. KELLER, M.D.
SUPERINTENDENT AND SURGEON OF THE STATE HOSPITAL FOR INJURED PERSONS OF THE MIDDLE COAL FIELD OF PENNSYLVANIA, HAZLETON, PA.

Case I.—Mary B., twelve years of age, was admitted to the Hospital, October 21, 1893, at 9 P.M. Four hours before admission, while standing by the side of a butcher's wagon, she was shot in the abdomen by the accidental discharge of a 38-caliber revolver in the pocket of the butcher. On admission, an examination showed the bullet to have entered the abdomen about four inches to the left of the median line in the lower umbilical region, its course being downward and outward. The abdomen was considerably distended, the temperature 98.2°, the pulse 132 and weak, the respiration 36. Preparations were immediately made for operation, and the patient was placed under ether. An incision eight inches in length was made in the median line and the intestines were exposed; the cavity was filled with blood. Seven distinct perforations were discovered: five in the small, and two in the large intestine at the sigmoid flexure. These were all closed with fine silk, the Lembert suture being used. The bullet had imbedded itself in the muscles of the pelvis; it was not discovered by probing and was allowed to remain. There was considerable bleeding at the point where the bullet had penetrated the muscles, which was checked by suturing.

An interesting feature in connection with the perforations found in the small intestine was the presence of an intestinal worm, a lumbricus, eight inches long, which had been cut in two by the bullet.

The abdominal cavity was thoroughly cleansed, a glass tube was inserted for drainage, and the wound closed. The girl reacted quickly from the operation, and the following temperature-range was between 98.2° and 100°. On the second and third days the patient vomited dark-green material. The tube was removed at the end of forty-eight hours. On the fourth day there was a large, well-formed bowel-movement. The treatment was very simple; with the exception of small doses of morphin administered hypodermatically the first three days for restlessness, no drugs were given. Silkworm-gut was used in suturing the abdominal incision and the stitches were removed on the ninth day. This case resembles the celebrated one of Dr. Bull, of New York, who, as mentioned by Greig Smith, in 1885 operated on a patient with seven perforations, with recovery.

Case II.—Anthony S., twenty-two years of age, was admitted November 25, 1893, suffering with a punctured wound of the abdomen. Two hours before admission, while working in the mines, he slipped and fell on his miner's needle, the needle penetrating the abdominal cavity to a depth of six or eight inches. This needle used by the miners in preparing blasts is a sharply-pointed rod of copper or steel about three feet long. The needle was withdrawn by his companions, and he was immediately conveyed to the hospital. While on the way he vomited several times and complained of intense pain in the abdomen. On admission he was found to be suffering acutely, with the belly somewhat distended, and the pulse rapid. Only a very small wound was discovered, about three inches to the right of the umbilicus. Under ether an attempt was made to probe the wound, but the probe could only be inserted a depth of one inch, owing to a laceration of the abdominal muscle made by the needle. An incision was then made in the median line and the tract of the needle exposed; from this point the probe readily entered the abdominal cavity. The cavity was opened by a seven-inch incision and found filled with blood. Three perforations were discovered: two in the mesentery, which had caused very free hemorrhage, and one in the small intestine; these were closed with fine silk. The needle in entering had bruised the omentum, leaving a dirty tract on its surface. The cavity was thoroughly cleansed, and owing to some slight hemorrhage that still existed a glass tube was inserted for drainage. The abdominal incision was closed with silkworm-gut.

Recovery was uninterrupted, the temperature never going above 101°. The tube was removed at the end of forty-eight hours. The bowels opened on the fourth day without the use of salines. The stitches were removed on the ninth day.

THE TREATMENT OF PTOMAIN-POISONING BY MEANS OF SUBCUTANEOUS INJECTIONS OF BLOOD-SERUM.

By C. F. DARNALL, M.D.,
OF LLANO, TEXAS.

On October 19th I was called to see a pair of twin babes, females, ten weeks old, who were being artificially fed, and who had been seized the day before with vomiting and diarrhea. Upon inquiry it was found that these symptoms had set in after partaking of a newly-opened can of condensed milk. The children presented the symptoms of ptomaïn-poisoning, and in the course of four days the weaker one died. With the able assistance of Dr. H. W. Moore, of Llano, I injected subcutaneously four ounces of a normal saline solution into the surviving twin, but without beneficial result. Four ounces of blood were on the fourth day taken from the arm of the father, a stout, healthy young man, quickly defibrinated, and two ounces of the serum were injected beneath the skin over the abdomen of the surviving infant. The child was carefully watched, and reaction occurred in about six hours. Improvement gradually took place, and in six days, upon a diet of thin corn-meal gruel at first, later replaced by fresh milk properly prepared, the child was well. It was placed at the mother's breast at regular intervals, and at the time of this writing, nearly nine weeks after the onset of the illness in the children, the lacteal secretion is fully established.

The operation was merely experimental, as the babe was apparently moribund, but it demonstrated what an artificial appropriation of blood will sometimes accomplish. We used a hypodermatic aspirator with a two-

way stop-cock and needle, a clean soft-rubber catheter for the supply-pipe, and clean bowls, teacups, and broom-straw. Everything was rendered aseptic with boiling water. Three needle-punctures were made; the serum went into the babe's circulation at once, and no inflammation of the cellular tissue, or skin, or any other untoward symptom appeared.

The query arises: Was the risk increased by using blood from one so many years older? No time was at hand to select a more suitable donor; he was the child's father, anxious for the operation, and the merits were not discussed.

Many a case comes to every practitioner suitable for subcutaneous injections of blood-serum—inanition and anemia, shock, hemorrhages, and collapse in fevers. The operation is simplicity itself, and with very little risk, as compared with intra-venous injections and direct transfusions, so that everyone should be prepared to do it at once when indicated.

A FATAL CASE OF HYPEREMESIS GRAVIDARUM.

BY BOARDMAN REED, M.D.,
OF ATLANTIC CITY, N. J.

DR. CLARA T. DERCUM'S case, so well reported in THE MEDICAL NEWS of December 9th, reminds me of an experience of my own occurring four years ago. A delicate, anemic woman about thirty years old had been pregnant several times and always experienced severe and persistent nausea and vomiting during most of the time till relieved either by delivery at term or prematurely. She claimed that once at least, and I think twice, she had had pregnancy terminated artificially by reputable physicians on account of the serious character of her vomiting. I was called to see her when she was at about the second month, and I found nausea and vomiting persistent and extreme. Examination showed some congestion about the cervix, and following the practice of Dr. Jacob Price, of West Chester—which had proved successful in my hands in several cases previously—I applied a strong solution of nitrate of silver to the entire external part of the cervix. The usual medicinal measures were also resorted to, the diet being meanwhile strictly regulated. There resulted a marked improvement in the patient's condition. The vomiting was almost entirely controlled, and my visits were stopped or made only at long intervals. A little later the woman went out with a sailing party on the ocean and at the same time indulged in some particularly indigestible article of food. Naturally there was a return of the illness and, as in Dr. Dercum's case, the condition after recurrence was much worse than before. Everything possible was done again, but without avail. I had the assistance of Dr. Gadd, of Philadelphia, and at different times Dr. Franklin, of Philadelphia, and Dr. Kaemmerer, of Atlantic City, saw the patient in consultation with me. The woman was fast becoming exhausted and it was finally decided to dilate the cervix under strict antiseptic precautions, and if this did not relieve the vomiting, to proceed to empty the uterus. The dilatation sufficed of itself to bring on labor, and within a few hours the fetus, which had progressed to about the third month, was delivered. Almost immediately afterward the patient sank into a condition of extremest exhaustion, with high fever, and died in spite of all the possible measures which were resorted to for the purpose of stimulating and supporting her. She was too far gone when delivery took place to bear the additional shock of curetting and washing out the uterus, or this also would have been done.

I have been induced to report this case by reading of the exceedingly narrow escape that Dr. Dercum's patient had under similar circumstances. The question strongly suggested by these cases is: Why should we wait till our patients are so nearly moribund before relieving them by emptying the uterus? The life of a wife and mother is infinitely more important than that of an unborn babe, even when known to be alive and near full term, and to risk such a life out of consideration for a fetus in the early months of pregnancy ought not to be thought of for a moment. In my case the family demanded that an abortion be produced when I was first called, and their eagerness to have the pregnancy terminated under any circumstances probably made all of the physicians in attendance more conservative than we would otherwise have been. In a practice of nearly sixteen years this is the only parturient woman that I have ever lost, and under similar circumstances again I should certainly counsel emptying the uterus after all the other possible remedies had failed to control violent and persistent vomiting, without risking much delay.

MEDICAL PROGRESS.

Uretero-ureterostomy.—KELLY (*Bulletin of the Johns Hopkins Hospital*, vol. iv, No. 34, p. 89) has reported the case of a woman, twenty-five years old, in which hystero-myomectomy was performed in the treatment of uterine myomata. After the round ligaments and the ovarian arteries and veins had been ligated and the broad ligament opened and its parietal layers pushed to the front and back of the pelvis, a large flat vessel, rather more than a third of an inch in diameter, was seen coursing on the anterior surface of the enlarged uterus for a distance of nearly three inches. This vessel closely resembled an engorged vein, and as it apparently terminated in the congeries of vessels at the cornu uteri it was ligated in two places and divided between the ligatures. It was at once seen that the vessel was a ureter. To repair the breach the lower portion was ligated close to its cut extremity and a longitudinal incision, a little more than a third of an inch long, was made in its anterior wall. A fine silk suture was then passed through the lateral wall of the lower portion, about a fifth of an inch below and posterior to the angle of the slit, and brought out through the slit and caught in the outer coats of the upper portion of the ureter close to its margin; this suture was then carried back into the slit and through the wall of the ureter close to the initial point of entrance. A similar suture was passed at a point directly opposite. By making traction on these sutures, while holding the slit open, the upper portion of the ureter was readily invaginated into the lower. These sutures were then snugly tied. In order to avoid the danger of urine backing up through the incision the edges were sutured to the invaginated portion with ten fine silk rectangular sutures, which included only the

outer coat. The loose peritoneum in the anterior part of the pelvis was now drawn over the field of operation and attached to the posterior surface of the stump and the broad ligament by a continuous suture, except at a point where the ureter was united. Here two pieces of gauze were laid over the anastomosed ends and brought out at the lower angle of the wound, to insure drainage of the urine in case the operation was unsuccessful. The remainder of the incision was closed in the usual manner. At no time after the operation was there the slightest urinary odor detected on the dressings, and on the third day the gauze drainage was removed. The patient had no nausea or headache or other untoward symptoms and the convalescence throughout was uninterrupted. The abdominal sutures were removed on the eighth day, the wound having united by first intention. The woman was catheterized every three hours for the first day; on the second she passed urine voluntarily, and thereafter the catheter was no longer used. The patient got out of bed on the seventeenth day and was dismissed, in excellent health, six weeks after the operation.

Circular Craniectomy.—Dumont (*Correspondenzblatt für Schweizer Aerzte*, 1893, No. 23, p. 778) has reported the case of a female infant, fourteen months old, in which circular craniectomy was performed for the relief of microcephalus. The child was the first-born of healthy parents and without hereditary predisposition. The birth was normal, although the labor was somewhat protracted. The child weighed six and a half pounds, and for the first two weeks presented no abnormality. At the end of this time it seemed to stop growing and to become dull. At the end of two months it commenced to roll its eyes upward, so that only the sclerotics were visible. At the same time slight twitching made its appearance at various parts of the body. At the age of four months the twitching was attended with cries. The convulsive attacks augmented in frequency and intensity, consciousness being at times lost three or four times in succession. After such an attack the child appeared for some time exhausted, depressed, and pallid. The head was rather conical and the fontanels closed. The eyes were turned inward and upward. Not a tooth was visible in the jaws. The hands and feet were cyanotic and deformed by contractures. The child bored its head into the pillows. Crying was attended with a peculiar snoring sound, and swallowing was accomplished in jerks and with difficulty. The distance from the root of the nose to the external occipital protuberance measured nine inches, from one ear over the vertex to the other ear slightly more than ten inches. The condition was diagnosticated as one of microcephalus, with premature ossification of the cranial sutures and epileptiform attacks, and craniectomy was advised and acquiesced in. Accordingly, an incision was made in the scalp, extending in the middle line from the forehead to the external occipital protuberance. The scalp, with the periosteum, was turned back and a trephine-opening an inch in diameter was made below either parietal protuberance. From this point the bone was gnawed away with forceps and saw forward and backward until the vertex was freely movable. The scalp was then replaced and sutured and an antiseptic dressing applied. The operation lasted an hour, and was followed by manifestations of collapse, which, however, disappeared in the course of a short time. After the lapse of several days the child slept and drank better. The wound in the scalp closed by primary union, and no further convulsive attacks occurred. The cyanotic appearance subsided and the strabismus became less marked. Two months after the operation the vertex of the skull was still movable; incisor teeth had appeared in the upper and lower jaws; the strabismus had become much less marked; there appeared to be some signs of intelligence; and no convulsive attack had taken place.

THERAPEUTIC NOTES.

Caffein-chloral is recommended by Ewald (*Deutsche med. Wochenschrift*, 1893, No. 50, p. 1343) in aqueous solution for subcutaneous injection in doses of from 3 to 6 grains, in the treatment of obstinate obstipation. If necessary, the injection is repeated after an interval of two hours. As a rule, liquid stools follow in the course of a few hours. The injections give rise to no pain, although a sense of burning persists for from one to three hours at the site of the injection. Relief of the muscular pain and articular swelling of rheumatic conditions has followed the injections. Caffein-chloral is a molecular combination of caffein and chloral, and appears in colorless, shining scales readily and abundantly soluble in water. In the presence of alkalies caffein and chloroform are set free.

Methylene-blue in Beri beri.—Thur (*Gen. Tijd. voor Nederl. Indie; Schmidt's Jahrb.*, Bd. ccxl, No. 40, p. 233) has employed methylene-blue in doses of 3 grains, given twice or thrice daily, in the treatment of eleven cases of beri-beri, with excellent results. The general condition was rapidly ameliorated, while the respiration became quieter and deeper, the pulse diminished in frequency, became fuller, stronger, and more regular, and the appetite and sleep were improved. Continued administration of the drug was followed by increase in the secretion of urine and diminution of the anasarca, and a favorable influence was exerted upon the excretion of albumin.

For Influenza.—

℞.—Camphoræ . . . . gr. lx.
Tinct. iodi . . . . ♏lx.
Mucilag. acaciæ . . . . f℥iv.
Glycerini . . . . f℥vj.
Olei menth. piper. . . . ♏vj.
Syrup. zingiberis . . ad f℥iij.—M.

Two teaspoonfuls every two or three hours.

INFLUENZA.

MANY physicians have contended that influenza is a permanent visitor among mankind; that there is no year and no season of the year when a few cases of it do not come under the hands of every physician, but that it is only at certain periods, when circumstances not yet recognized combine to induce greater virulence of the poison of the disease and more widespread susceptibility among the people, that the affection is generally recognized. At other times the cases are called by various names, according to the more prominent symptoms: now gastric catarrh, now typhoid fever; now catarrhal pneumonia; now nervous fever; now bronchitis, and so on.

Conversely, it is doubtless true that in periods of severe epidemics, and especially in periods of pandemic, the name "grip," or "influenza," is applied to ordinary catarrhal affections not properly coming under that heading, so that, as was said several years ago, before the pandemic of 1889 and 1890 had once more attracted the attention of medical men in general to the disease: "To the classic paradox of the prognosis of catarrhal fever, 'the most fatal and the least fatal of all diseases' (DA COSTA), may be added a similar characterization of its diagnosis—at once, the easiest and the most difficult. The picture of a typical attack of influenza is so striking that to mistake it were almost impossible; but typical attacks are by no means so frequent, save in periods of widespread epidemics, as the irregular, ill-defined, misleading manifestations that occur without attracting prominent professional or popular attention."

Among the diagnostic symptoms upon which stress may be laid in cases of influenza exhibiting involvement of the respiratory apparatus are the following:

The amount of respiratory distress is frequently out of all proportion to the physical signs elicited upon percussion and auscultation. Resonance may be perfect, or there may be even hyper-resonance upon percussion over an area wherein auscultation fails to detect any respiratory murmur, normal or abnormal. This mechanical condition can only be explained upon the theory of SIR B. W. RICHARDSON, that the pathologic condition is a "pneumo-paresis." The alveoli are distended and contain air, yielding resonance on percussion, but they fail to alternately contract upon expiration and re-dilate upon inspiration, so that the contained air is motionless, and thus auscultatory phenomena are absent.

In other cases, while numerous abnormal sounds are discovered at scattered areas throughout the chest, yet they do not indicate a degree of involvement of lung-substance sufficient to account for the dyspnea and other symptoms of failure of respiratory function—and here again the theory of a paretic condition must be invoked to explain the phenomena. In still other cases there is an excessive sense of constriction of the chest, or there is frequent harassing and ineffective cough, only to be explained by the theory of nervous irritation. In addition to these symptoms "the chilliness, the irregular fever, the rheumatic pains in the back and limbs, the unaccountable depression, the exquisitely painful headache, the cutaneous hyperesthesia, often the precedent history of a coryza, sometimes coincident conjunctivitis, occasionally neuralgia, supra-orbital or infra-orbital—many or all of these phenomena being easily elicited upon close observation or questioning—will inform the careful physician that he has more than an ordinary "cold" to deal with.

A greater liability to error in diagnosis exists, however, when catarrhal symptoms referable to the nose, throat and chest are slight or unnoticed, and the alimentary canal or the nervous system bears the

brunt of the disease. Unquestionably many cases have been reported from time to time as instances of "typhoid fever," and much success in treatment, even in aborting the disease, has been ascribed to this, that, or the other indifferent remedy or therapeutic method, when in fact the affection dealt with was catarrhal fever of the enteric variety. Discrimination in the first few days of the attack may be difficult, perhaps impossible; yet there are many things, perhaps trifles, intangible it may be, save to the experienced observer, that may assist in the differentiation even in the preliminary stages. In influenza the tongue is not characteristic (although a peculiar pearly whiteness has been described); the physiognomy is not that of typhoid fever; enlargement of the spleen is uncommon, to say the least; while the weakness of circulation, the general depression, and the headache are greater than would be expected in a case of typhoid fever so mild in other respects. There is no typhoid odor to the breath; the temperature is decidedly irregular—perhaps much higher than would be expected in an early case of typhoid fever, perhaps quite low—but in either event subject to extreme and rapid fluctuations without therapeutic intervention. One highly significant circumstance in connection with the fever of influenza is the comparative comfort with which patients endure temperatures that in almost any other affection would be quite alarming. Though the thermometer register 105° or 106° F., the patient will be scarcely conscious that he has fever. In some cases, it is true, his head will ache tremendously, but stupor is absent and no consciousness of abnormal heat seems to be experienced. When we consider, moreover, that in some of the most prolonged and severe cases of influenza the temperature is low, and indeed frequently subnormal, it would seem that in this disease the Hippocratic maxim that fever is evidence of Nature's reaction against infection is eminently true. We have already laid stress upon the paretic symptoms affecting respiration and circulation—the great functions of organic life. With the depression of these functions depression of temperature is intimately connected, the more so when morbid sweating is a part of the syndrome.

From this a valuable therapeutic lesson may be derived. The similarity between the effects of antipyrin and the effects of influenza-poison is great; both depress vital functions by a direct blow at the vital centers in the medulla. If, then, any drug is *not* to be used in the treatment of influenza, it is antipyrin. It is true that the drug may be safely administered upon the principle of *similia similibus curantur*, in the infinitesimal doses which are proper for drugs given upon that principle; but in doses which are likely to have any effect upon the patient the use of antipyrin can only be harmful. Of phenacetin and acetanilid the best that can be said is that they are less likely to do harm than is antipyrin. Of no one of the coal-tar products can it be truthfully said that its use in the treatment of influenza is either necessary or beneficial.

Varying somewhat with the type of the symptoms, the general treatment of influenza should be conducted upon supporting and eliminative lines. Rest is the first requisite, even in mild cases; for mild cases improperly managed are likely to prove severe, or to be followed by distressing sequelæ.

The patient being put to bed, profuse diaphoresis should be induced if possible. The simplest means is to have the patient take a hot bath before going to bed and then to wrap himself up in blankets, with or without the additional use of hot air, steam, etc. Diaphoresis may be favored by the administration of spirit of nitrous ether, of potassium nitrate, or even of Dover's powder. Diuresis should be stimulated by the administration of sodium benzoate, which is the nearest to a specific drug in the treatment of influenza among the many that have been brought before the profession. It may be given in doses of from ten to twenty grains at intervals of from two to three hours. Strychnin sulfate or strychnin arseniate should be given from the first in small doses, say $\frac{1}{120}$ of a grain at intervals of from one to three hours, to be increased should the conditions seem to demand it. In many cases this will be the only treatment necessary. In others, phenyl salicylate, cinchonidin or quinin salicylate, sodium salicylate or ammonium salicylate may be used, the last-named being particularly applicable when there is pulmonary involvement, the first-named when there are enteric symptoms. In some cases a better effect will be obtained through making up the required dose of salicylates (from twenty to sixty grains daily) by a combination of several salts than through the use of any one alone. When feebleness of the heart is a prominent symptom and it is not considered desirable to increase the dose of strychnin or to depend upon strychnin alone, caffein is the most useful of the cardiants. To old per-

sons, and when pneumonic complications become severe and threatening, strychnin should be given in large doses. Under the latter conditions ammonium should also be freely exhibited, and inhalations of oxygen should be given persistently. We have seen more than one life saved by oxygen-inhalations, resorted to in time and kept up faithfully. A few whiffs of the gas will not answer; one must be prepared to waste several cylinderfuls if necessary. The value of hot applications to the chest in the early stages of the pneumonia of influenza, or of the pleurisy which is often associated therewith, cannot be too strongly insisted upon. The old-fashioned flaxseed poultice is probably the best means of applying heat to this region. It increases the comfort of the patient and favors resolution. For the relief of pain, and especially of headache, nothing has proved in our hands equal to hyoscin hydrobromate, the dose varying from $\frac{1}{200}$ to $\frac{1}{50}$ of a grain, repeated in two hours if necessary. In some cases inunction with aconitin oleate (2 per cent. solution in oleic acid) has been necessary to relieve the distressing supra-orbital neuralgia; the application, of course, is made over the seat of pain, and but a drop or two drops of the solution are employed at a time. We have said nothing of diet, taking for granted that the importance of proper alimentation is understood, but we cannot conclude without emphasizing the necessity for giving the patient plenty of pure water to drink. Alcohol is necessary in a few cases, and, when necessary, it should be given in such doses as seem to be indicated. Its routine and excessive administration in every case is to be strongly deprecated.

THE SANITARY BEARINGS OF SMOKE-NUISANCE.

SMOKE is unquestionably a great nuisance. Those who live near abundant supplies of smokeless fuel, as is the case in most of the larger cities on the Atlantic seaboard, find the sooty atmosphere of Western cities quite distressing. Apart, however, from the actual discomfort, it is worth inquiring if any direct injury to health results from constant living in a smoky atmosphere. Even assuming that the solid particles of the soot are retained in the lungs, we can scarcely assign to such particles a power to develop specific disease. We are, of course, not indifferent to the dangers of dust as a conveyor of contagion; but it is in the dust of human origin, indoors, and of manurial refuse, out of doors, that we will find the microbes of tuberculosis, pneumonia, and diphtheria. The minute masses of carbon or of solid hydrocarbons which pour out of the furnaces in which soft coal is used are thoroughly disinfected by the condition of their formation, and they are not likely to acquire any infection by passing through the air.

Nevertheless, we can scarcely afford to look on smoking chimneys as of no sanitary moment. Everything which diminishes the force of sunshine, or which discourages cleanliness, must be regarded with suspicion. Now, the smoke-nuisance does both these, and works unfavorable conditions also indirectly, for the deprivation of sunlight compels a resort to artificial light, and this at best is not without insanitary influences. Moreover, in the ordinary form of artificial light—gas-light—a material vitiation of the air occurs, not only by the removal of oxygen and addition of carbon dioxid, but a notable proportion of sulfuric acid is usually produced, for it appears from recent researches that in the form in which sulfur commonly occurs in coal-gas it burns directly to sulfuric acid, and not to sulfurous acid, as was formerly supposed. Thus there is formed a gas highly irritating to the lungs, and likely to bring about a catarrhal condition which will render the lung-tissue less resisting. Motives of economy will also lead to efforts at conducting work without sufficient light, and thus will come injury to the eyes.

It does not appear, however, that these circumstances materially increase the mortality. London and Chicago may be taken as examples of smoky cities, but the death-rate in both is quite satisfactory. The death-rate in the latter city was formerly quite high, but this was due to typhoid fever, which has been somewhat abated by a better water-supply. It is, however, a dangerous system of reasoning to assume that because sanitary conditions are good they could not be improved. We may admit that the statistics of London and Chicago show that no very serious addition to mortality is due to constant smokiness, but it is not unreasonable to suppose that these and all similar cities would be benefited by a clear atmosphere.

So prominent has this consideration become in London that *The Lancet* has caused a scientific commission to inquire into the best method for smoke-prevention. It is to be regretted that the names of the members of the commission are not given, and also

that there seems to have been a very close association between it and a certain gas-manufacturing corporation; but the general conclusions are sound and the scientific details interesting. The commission favors the use of gas as fuel, and shows that under proper construction of stoves and ventilators no dangers to health ensue. The rapid progress in applied science at the present day is well shown by the fact that this report leaves out of consideration that form of heating which is already practicable, and which bids fair at an early date to supplant to a great extent the direct use of fuel, namely, electric heating.

We can, indeed, foresee that at no distant day such energy as is to be obtained by coal will be produced at the mines and transmitted to centers of population in the form of electricity, to be again converted into light, heat, and power. The sanitary gain that will thus result will certainly not be inconsiderable. The avoidance of smoke, ashes, deleterious gases, bulky fuels, and care of furnaces must certainly tend to increase the duration of life and to make it more enjoyable.

THE NEED OF PUBLIC MEDICAL LIBRARIES.

There are few things that a man can do so certain never to result in aught but good as the founding or endowing of a public library. Neither is there a surer way than this to secure honorable fame and an immortality of good repute. If this is so as regards more or less ephemeral general literature, how much more is it true of medical literature? Here it is of the very first importance that reference to the literature of the past shall be easy of access to every worker in medicine. But in the face of this self-evident truth there is another fact no less sadly self-evident: the remarkable want of medical libraries. Few can realize the value to the profession, and through the profession to the world at large, of such libraries as that of the Surgeon-General at Washington or that of the College of Physicians of Philadelphia. But outside of these two noble institutions there are hardly any other first-class medical libraries in the United States. There should be thousands. The result is that every physician finds it one of the severest taxes on his scanty earnings to supply himself with but a portion of the books and periodicals he should be able to consult.

There are many cities of our country whose physicians, instead of establishing a common library, spend more money independently and unsatisfactorily for books than would be required to provide a satisfactory library for the entire local profession. There are but few physicians who can afford to buy the great encyclopedias and reference-books wherein are gathered the sum of medical experience. These a public library could supply.

And what a means of labor-saving to these physicians such libraries would be, and indirectly what professional and scientific help they would yield! The "unique cases" would find their proper pigeon-holes and be recognized as one of a hundred other "unique" cases. The inventors and discoverers of a useless experiment, of a new drug, of a novel treatment, or of a clinical mistake, would often be spared unnecessary pains and costly disappointment by a glance at a good catalogue or at the *Index Medicus*.

Professor Nicholas Senn, of Chicago, has lately presented his great collection of medical books to the Newberry Library. There is nothing that will in future more redound to his fame than this splendid munificence. All honor and gratitude to him! We take pleasure in also recording the fact that Dr. Robert Battey, of Rome, Ga., the distinguished gynecologist, a few months ago offered his private library, consisting of about a thousand volumes, to the Governor of Georgia as the nucleus of a State library to be established at Atlanta.

Philadelphia awaits some such generous gift to double the usefulness of her already great medical library. Every city of the land also needs such gifts. Even the smallest cities could combine, incorporate, and make the nucleus of a library, and thus render it possible for legacies and gifts to be offered, with a certainty that the generosity would be cared for and put to the uses designed. As the older physicians, the revered masters of the guild, who have attained competence or even moderate wealth, one after another, foresee the approaching "great silence," they will thus be glad to remember with gifts of books or money the younger men into whose hands they must yield their office; and, as we have said, there is no better way in which they can do their profession and themselves the honor each deserves than to put at the service of their heirs the gathered and systematized wisdom of the workers of the past.

Let us found new medical libraries, and let us fill the empty shelves of those already founded!

EDITORIAL COMMENTS.

"Blue-Blooded Aristocracy."—There are a great many expressions in our language, and in every language, that seem to have no meaning. One wonders why, generation after generation, people keep repeating them, everybody at the same time wondering how they came into existence. It has been the delight of antiquarians delving in the musty records of the past, to hunt out some custom or fact that throws light at once upon the life of the past and fixes in the minds of the present a luminous explanation of the origin of some philologic curiosity. Sometimes the explanation is not forthcoming, because, lying so near at hand, it cannot be found by antiquarians. There is one such expression that by its very name implies a physiologic or pathologic origin, and yet, so far as we know, has never been explained or sought to be explained as due to any physiologic cause. This phrase, "blue blood," as applied to aristocratic folk, seems a palpable absurdity, because, physiologically, of course, the constituents and color of the blood of aristocrats cannot differ much from that of working and plebeian people. How, then, did it come into use?

Every oculist of any alertness and closeness of observation-powers must have daily noticed, as school-imprisoned and behoused patients come into his office, the fact that in women, girls, and children, severe and long-continued eye-strain produces leanness and pallor of the temples, with the blue veins plainly visible at ten feet distance. Sometimes these blue lines of the temples—as indicative of eye-strain as those of the gums are of lead-poisoning—curl down beneath the eye and along the cheek. Every oculist must have also noticed how soon after getting proper spectacles the temples fill out, the blue lines disappear, and the whole expression of the eyes and face changes. Pain, suffering, malnutrition, at once disappear. The appetite, especially for breakfast, long lost, returns, sleep is quiet and refreshing, and growth recommences. A tremendous difficulty has been overcome and life, as it were, is again resumed.

In the Middle Ages especially, but also in modern times, women, girls, and children of the upper classes have been housed more than the men and older boys. This housing necessitates continuous employment with books, sewing, or other ocular labor at near range. The ametropia that with out-of-doors living can be borne by the compensatory powers of the organism cannot be endured when there is added the extra burden (and, evolutionally, the abnormal function) of continuous accommodation or work at near range. Hence anemia, the pallid skin, the "pinched eyes," the blue or the swollen veins of the temples, blue circles about the eyes, etc. Heredity of these abnormal eyes—a most common fact—coupled with the inherited subnormality of general nutrition that results both from the ametropia and the lack of physical exercise, does the rest of the work, and the daughters and wives of the castle-owners and of the rich are at once seen to be "blue-blooded." But the explanation shows the fact to be a sign of disease and a thing to be ashamed of, not, by any means, one to be proud of.

Promised Foot-ball Reform.—To one who can read between the lines, the actions and arguments of the foot-ball advocates are furnishing a constant source of excellent amusement. They are bound to take note of the arguments moral, educational, and physiologic, against the game as it has existed, but more especially are they forced to consider the profound wave of popular indignation rising against past excesses. Instead of a means of attraction of students it is quite possible that the game may cause subtraction. In this dilemma a way out has been found by reluctant acceptance and forced advocacy of reform. Reform is promised, but the funny part comes in when we note the ill-concealed disgust at the nauseous dose. However, the critics of foot-ball excess may rest satisfied with their work, if reform of the rules be really brought about, and if it be such as to do away with the evils of the game. This will be the critics' work, and this is all they have wished. "Reform within the party" was not tried spontaneously, and has only been promised by force of compulsion, criticism and popular feeling from without. The critics may also point out that the speciousness of the logic so far offered in defence is apparent in the fact that every line of the argument could be applied in favor of boxing. Indeed, in the late magazine defenses of the game every time the word *foot-ball* occurs, it could be replaced by the word *glove-fighting*, with equal and even with sounder logic. The difference of acceptance of the logic consists solely in the fact that foot-ball is the fashionable fad of the day and prize-fighting is not. There will never fail able, at least plenteous, defences of the customs and demands of the *Zeitgeist*. Every English Bishop, the powers, votes, and logic of the Established Church (by name, of Christ, and of Religion) arrayed themselves against the abolition of slavery—all of which does not affect the fact that slavery was wrong, unchristian, and irreligious. To flatter the *Zeitgeist* and "the powers that be" is pleasing to that fickle and faithless tyrant, and, temporarily, very, very profitable to the flatterer. But, again, flattery, applause, profit, and honor cannot alter the facts that, as carried on of late, foot-ball has not been in the interests of true athletics or genuine physiologic culture, and has been very far from furthering the clear purposes of education and of educational institutions. Hence when the advocates of the game (however grudgingly and slurringly) acknowledge the past abuses, and promise such reform as will do away with these abuses, we warmly cry them welcome, and beg pardon for any "excess of zeal" on our part. We are all, it seems, in favor, and most heartily too, of the best and most perfect development of the human body; but we protest that this must be consistent with, nay, subordinated to, the best and most perfect development of the human mind.

The Source of Some Therapeutic Enthusiasms. — It has often been noticed what reckless belief in a therapeutic agent is aroused by self-interest. We have before us a circular that tells the story of both the zeal and the motive in a charmingly naive manner. The title announces the absolute curability of epilepsy by means of a certain drug that, as we read, we judge can only be procured from the author of the circular. The absolute cure is founded upon the author's experience in two cases of cure, one of which has lasted three months. On one page we are assured that the plant that yields the drug

is not a nettle; on another page it is called a nettle. Our esteemed fellow-townsman, Dr. Guy Hinsdale, is said to be in charge of the State Hospital of the only State that provides for its epileptics, viz., New York, and that therefore "he treats more cases of epilepsy than any other medical man in the country." It is not, of course, pretended that Dr. Hinsdale has the most remote connection with the "treatment," the drug, the drugger, or the institution-founder. His name is merely mentioned to give dignity to the circular. There follow a number of reports of cures by physicians who have ordered their stock of the drug from the enthusiastic essayist.

Then comes the funny part: It is the drug alone that cures, and yet "it is impossible to treat epilepsy successfully at home or in private families," and hence "I have opened a large sanitarium, with all modern improvements," and so on, "where the patients that have been unsuccessfully treated by Weir Mitchell and other eminent physicians," etc. Don't let us hear anything more about a lack of humor in physicians. However, there is bitterness at the end of the laugh in thinking that such stuff is from a "regular" irregular, that it was all first published in a so-called medical journal, and that the fellow will probably make much money.

Municipal Supervision of the Milk-supply and the Meat-supply.—The little town of Mansfield, Ohio, has set an example in municipal sanitation that other and larger cities might follow with advantage. From the Fifth Annual Report of the Health Department, covering the period from March 1, 1892, to February 28, 1893, the mortality rate was 10.5 per 1000, a reduction of more than 3 per 1000 as compared with the preceding year. As the result of recent legislation, the milk-dealers of the city are all under the care and observation of the Health Department, and when it has been necessary to do so, such regulations have been prescribed as to the keeping of the cows, the care of the milk, and of the necessary utensils, as have been thought best by the department in the interest of the welfare of the community, and when milk-dealers have failed to comply with these instructions they have been promptly prohibited from selling milk in the city. On the other hand, when there existed a suspicion that the milk was not pure, specimens were examined, and, if found impure or diluted with water, the further sale was interdicted until the defect was remedied. Meat-dealers are also by law required to register with the Health Department, under whose control they are, and whose duty it is to look after the sanitary condition of the markets and slaughter-houses, wagons, and all of the necessary paraphernalia. In case a meat-dealer does not comply with the requirements of the Health Department, or is found selling diseased or spoiled meat, his permit can be revoked.

Meat-extracts. — *Food and Sanitation*, an English journal devoted especially to exposing adulteration, has recently been discussing the composition of some of the well-known meat extracts. The general conclusion that such preparations have little positive food-value is, of course, not new, as physiologists have recognized this fact for a long while, though they conceded to them a certain amount of stimulant quality. It is interesting, however, to note some of the analytic data furnished by the journal. An "Essence of Beef" is found to contain over 91 per cent. of water, and not quite 4 per cent. of albuminoids and peptones. The highest percentage (23.87 per cent.) of the latter principle is found in "Bovril," "Liebig's Extract" coming next (9.55 per cent.). In all the samples, the crystalline principles, kreatin, etc., are the most abundant solids, and these are not regarded as appreciably nutritious. Attention is called to the high selling-price of these preparations, which makes them enormously expensive forms of food. Incidental to the discussion of the question, *Food and Sanitation* also notes that Mr. Maybrick was fed on one of these preparations, and was possibly starved to death. Some glycerol found in Mr. Maybrick's house had arsenic in it, and it is stated on the authority of a Birmingham chemist that a considerable quantity of arsenical glycerol was sent into England from Germany. This last statement seems very remarkable, and if true, suggests a most dangerous and criminal adulteration.

An Argument for Cremation, offered by our esteemed English contemporary, *The Medical Press and Circular*, is that in cases of apparent death, "cremation would obviously dispose of any chance of a person being buried alive, as the first touch of fire would effectually rouse the victim of any cataleptic slumber." In view of the method of practical cremation one experiences a creepy mingling of feelings of ghastliness as to the fact, and of ludicrousness as to the editorial logic. In close observation of facts and infallible induction from them, this is almost on a level with our contemporary's "arguments" against spelling-reform and about as mirth-provoking.

SELECTION.

THE MEDICAL PROFESSION AND THE HOSPITALS.

This is the time of year when the hospitals of the city recite their deeds to the public and ask for money to carry on their work. It is a time when the question of the utility of this work is presented eloquently to everyone. As a rule, New York responds to the amount of about $50,000. No kind or degree of solicitation is able to raise the sum much above this, and it has in the last year fallen off slightly. New York has forty-seven hospitals, perhaps more if we include the private and semi-private institutions. These hospitals have eleven thousand beds, and the number of patients treated annually reaches up toward a hundred thousand. The number of hospitals and patients treated in them is increasing rapidly. It is safe to say that the amount of work done has doubled since 1875, and there is no sign of a decrease. On the contrary, during the past year large sums of money have been expended in erecting new hospitals or extending old ones.

The same rapid growth has been noted and commented upon in other cities, notably Cincinnati and Philadelphia. In the latter city there are, according to The Medical News, thirty-seven hospitals with four thousand five hundred beds, costing $1,300,000 annually. It cannot be denied that the medical profession has begun to look upon this movement somewhat critically, not to say coldly. This is due to several causes. First of all, the

treatment of medical men by hospital managers has always been arbitrary, and attended with friction and disturbances. Hospital authorities have heretofore often regarded the medical staff as a kind of necessary evil. They have taken advantage of the fact that physicians have desired to become attached to hospitals, to get as much as possible out of them with as little return as possible. The theory that a visiting staff should be paid for its work has been ridiculed, on the ground that plenty of men can be found who will work for nothing. This theory has a certain economic basis, we admit, but it is not an absolute one, otherwise why should it not be applied to positions of honor everywhere. We could get plenty of Congressmen, Senators, Presidents, and even judges, to serve for practically nothing. But still a more cogent reason for the growth of an antagonism to hospitals is the way in which they deal with the question of charity patients. It is becoming more and more the habit for surgical operations to be done in hospitals. Even well-to-do patients are sent there, paying perhaps nothing, or at any rate a fee very inadequate considering their means and the services rendered. As THE MEDICAL NEWS says: "Formerly a young doctor had a chance of being called to attend an accident case happening in his neighborhood. Many a physician has won his way into a fair practice through the skill shown in such emergencies. But to-day the patrol wagon or the ambulance is as speedily obtained as the nearest doctor, and the case is whirled off to the hospital. It is treated in the dispensary if a slight case, or sent to the wards or a private room, according as the financial condition of the patient seems to warrant. We have known rich men to pay $25 a week for a private room in a general hospital, and demand extra attention of resident and visiting physicians, without ever thinking of remunerating one or the other."

In the smaller cities the case is, we are informed, even worse. We have met well educated and experienced practitioners who have done much surgical work, and done it well, until the building of some small hospital, which is generally under some special political or religious auspices. This killed their surgical work at once. The spread of the hospital system is thus tending to throw a larger amount of medical work every year into the hands of corporations, and the trend is toward a nationalization or municipalization of medicine.

Now, this will certainly be disadvantageous to the physician, for it lessens the amount of his remunerative work, and tends to lessen the general skill of the practitioner. It will make the few skilful, the many unskilful and dependent. For all this physicians will have no right to complain, if the general effect is to be beneficial to the public. If it results in enabling more people to get better medical service at a lower rate, without pauperization or loss of self-respect, then we as good citizens must submit to the inevitable.

In our opinion, however, this will not be the result. If the rewards of the profession become less, its honors more uncertain, a poorer class of men will enter it. If advancement is difficult, ambition will be crushed out. In the end, therefore, the public health will be in the hands of a spiritless and mediocre bureaucracy. Surgeons will be but the machinists of corporations, and physicians clinical clerks to coöperative institutions.

We must deplore now, therefore, as we have in the past, the present tendency to the institutionalism of medicine.

The way out of it, as it seems to us, has already in a measure been begun. It consists in physicians themselves having charge of their hospitals and dispensaries, and in controlling their charitable work. Already two of our teaching institutions have their own hospitals; many, perhaps most, of our eminent surgeons have their private hospitals. The association together of a few physicians and surgeons in good practice enables them to equip a hospital of their own, and renders them independent of the favors of lay hospital-boards.

Perhaps this is not the only or the best way to fight against medical institutionalism, but it seems the most practicable at present. At the same time physicians, as a body, should demand more just treatment from hospital authorities, and should protest against the establishment and support of superfluous medical charities.—*The Medical Record*, January 6, 1894.

REVIEW.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN, FOR THE USE OF STUDENTS AND PRACTITIONERS. By JAMES NEVINS HYDE, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago. Third edition, thoroughly revised and enlarged. Pp. 802. Philadelphia: Lea Brothers & Co., 1893.

THE two previous editions of this work met with such general favor, both in this country and abroad, that we are not surprised that a new edition was so soon called for. The author states in the preface of the book before us that thirty-five new diseases have been considered. We find that the chapter on tuberculosis has been rewritten and enlarged, and that lupus vulgaris has been relegated to a position among the verrucous and other cutaneous manifestations of tuberculous infection. Among new chapters may be mentioned those on pityriasis rubra pilaris and keratosis follicularis; also, of less importance, those on epidemic dermatitis, actinomycosis, xanthoma diabeticorum, pemphigus vegetans, scarlatiniform erythema, and the parasitic forms of eczema. The new and original illustrations consist of five plates and twenty-two woodcuts.

It will thus be noted that much new and, we may add, valuable matter has been introduced, and after a careful perusal of the pages the conclusion is reached that the author has put forth a sound, practical, good work, a better one even than the previous edition. Quotations from the authors of all countries, but especially from our own, are liberally made use of, with numerous references, which add very much to the value of the book. On every page may be noted a frank expression of the author's own views on the many problems that are continually presenting themselves for solution, but nowhere do we find any trace of dogmatism or of undue self-assertion. As a result, we have a work written in the best possible style, which must commend itself to all. It may be added that Dr. Hyde is well known at home and abroad as an accomplished physician and a dermatologist of large experience. We take

pleasure in heartily commending his work to the profession. The field of dermatology has grown to such large proportions that no one but the educated and well-read specialist can now successfully cover the ground. If we were to make any criticism, our remarks would concern the title-page only, and we should say that so elaborate a work as this must appeal to the physician rather than to the student, who, as a rule, has difficulty in mastering even the rudiments of dermatology. It is a physician's and not a student's book.

A few excellent photographs and some other illustrations are introduced to portray certain diseases from a clinical point of view, while numerous woodcuts are made use of to explain the pathologic anatomy of some diseases. It is quite impossible to illustrate completely a work of this kind, dealing as it does with considerably over a hundred distinct diseases. The author, however, has made the best and judicious use of the pictorial material at his command, which, in most cases, is above the average in quality. The anatomy of the skin is particularly well illustrated.

NEWS ITEMS.

The Ohio College Association against Foot-ball and the Intercollegiate Games.—The following resolutions were adopted by the Ohio College Association at its meeting at Delaware, Ohio, December 28, 1893:

"First. In common with all educational authorities, so far as known to us, and in common with the press of the country and the opinions of our patrons, we deplore the roughness and exposure to injury which characterize the game of foot-ball as at present played, and urge the measures of reform in its rules and methods which we are glad to know are being considered in some influential quarters. And we furthermore suggest to the authorities of the colleges we represent to consider the propriety of suppressing the game unless the reforms be made and observed.

"Second. We would place on record our heartiest protest against the intercollegiate athletic games so far as they entail needless expense, so far as they interfere with study, so far as they tend to promote professionalism, and so far as they introduce an unwise competition, and we would recommend that each college of this association consider the question of the prohibition of the games.

"Third. We nevertheless heartily, and as the result of experience and observation, approve of the utmost exertion to secure thorough physical development for our youth in college by the most careful and scientific methods.

"We believe that the gymnasium furnishes a broad and sufficient basis for that pervasive athletic culture which those need who are to do life's work in directions of mental effort, and that sufficient variety can be found in the field-days and relative out-door sports with some military drill as an adjunct, and that ample interest can be secured by intercollegiate competition to obtain the most perfect results in the most agreeable manner."

This report was a compromise report substituted for the majority report of the Committee on Athletics and the Gymnasium; the majority report is described as having been "broad and sweeping" against all intercollegiate games of foot-ball and base-ball.

Prize of the American Neurological Association.—The American Neurological Association offers a prize of $200 for the best essay on any subject connected with neurologic science.

This competition is open to physicians who are legal residents of States in North and South America.

Essays must be sent to the Secretary of the Association, Graeme M. Hammond, M.D., 58 West 45th Street, New York City, on or before the 1st day of May, 1894.

Each essay shall be accompanied by a sealed envelope containing the name and address of the author, and bearing on the outside a motto, which shall also be inscribed upon the essay.

Essays shall be type-written, in either the English or French language, and with the pages securely fastened.

The Council of the Association reserves the right to reject any or all essays judged unworthy of the award.

Each essay must exhibit original research, and none will be accepted that has previously been published.

A Hospital for Contagious and Infectious Diseases in East Orange, N. J.—Articles of incorporation of the East Orange Hospital for Contagious and Infectious Diseases were filed at East Orange, N. J., on January 2, 1894, by Dr. William B. Graves. The purposes of the Association, as defined in the articles, are the care and cure of sick persons, especially those sick of infectious and contagious diseases, the training and education of persons to act as nurses, and the assistance of the needy poor of East Orange.

A Special Week in Diseases of the Heart and Lungs.—The Philadelphia Polyclinic has arranged to devote the week commencing January 22d to a series of lectures and demonstrations dealing with the diseases of the heart and lungs, with relation to their etiology, pathology, diagnosis, and treatment, special prominence being given to practical points of every-day utility.

A Four Years' Course in the University of Minnesota.—It is officially announced that the Board of Regents of the University of Minnesota has extended the course of study in the College of Medicine and Surgery from three to four years of eight and one-half months' duration. The new schedule of requirements will become operative in 1895.

BOOKS AND PAMPHLETS RECEIVED.

Report of Cases of Operative Relief of Endocranial Hemorrhage. By W. H. Hudson, M.D. Reprinted from the Annals of Surgery, 1893.

Tetra-Ethyl-Ammonium. A New Solvent for Uric Acid, Discovered at the Edison Laboratory. By Frederick Peterson, M.D. Reprinted from the New York Medical Journal, 1893.

A New Instrument for Controlling Tonsillar Hemorrhage. By H. Hoyle Butts, M.D. Reprinted from the Medical Record, 1893.

Hepatic Abscess, with the Report of a Clinical Case. By W. Blair Stewart, A.M., M.D. Reprinted from the Medical Bulletin.

Heredity: its Relationship to Mental Disorders. By Alex. L. Hodgdon, M.D. Reprinted from the American Medico-Surgical Bulletin, 1893.

ORIGINAL ARTICLES.

INSANITIES CHARACTERIZED BY DOMINANT CONCEPTS: WITH PRESENTATION OF CASES OF AN UNUSUAL FORM.[1]

BY ALLAN McLANE HAMILTON, M.D.,
OF NEW YORK CITY.

I WISH this evening to say a few words about the form of mental disease that is characterized by the continued existence of one or more dominant concepts which so influence the mental habit of the individual as to lead to the expression of fixed ideas that do not ordinarily rise to the dignity of delusions. Much has been written about this form of insanity, and it hardly seems necessary to refer in detail to the descriptions of Continental and American authorities who have given it the names of *Folie de doute*, *Grübelsucht*, and *Insanity of doubt*, or to the exceedingly curious and bizarre actions and utterances of its victims; suffice it to say that the imperative conception that enters into the production of *doubting insanity*, as Coombes-Knapp suggests, "plays as important a part as the delusion does in the genesis of paranoia."

It is my purpose more particularly to consider the clinical features of this form of insanity, rather than the psycho-pathology of the disease, which has received ample justice, especially at the hands of Knapp, Spitzka, Krafft-Ebing, and the earlier writers. In 1885 I described the psychosis, giving it the name *introspective insanity*, and defining it as a "vague condition of mental weakness in which there is slight derangement of the intellectual powers, yet a decidedly marked enfeeblement of the will, and excitement of the emotions of a more or less limited kind." Since then various writers, although differing somewhat in their calculations, have regarded it as a low grade of *degenerative insanity*, and Spitzka calls it an "abortive monomania." Westphal and Krafft-Ebing are decided in their opinion that it is a variety of *Verrücktheit*, while American writers, among them Cowles, are not disposed to regard the affection as one due to hereditary influences. My own experience, which has been considerable, has led me to the conclusion that in the majority of patients the malady is an insanity of evolution, and like paranoia it appears in subjects who present not only a history more or less pregnant with transmitted predisposition, but not rarely stigmata.

There are undoubtedly two forms of the disease: a respectable minority in which the persistent conceptions are limited in expression and form, and are either the exaggeration of a weakness that many normal individuals at times present, or are transient symptoms of hysteria, and often disappear under moral or medicinal treatment; and a second form which is a degenerative disease and usually incurable.

Although an attempt has been made to apply characteristic terms to mental vagaries of patients presenting this disorder, it is impossible, except in a general way, to differentiate them, although certain cases may be said to be dominated by groups of ideas, while at other times we find an association of imperative conceptions. The word "mysophobia" has been coined to designate that form in which the patient is in constant fear of contamination, and on every conceivable occasion washes his hands. "Délire de toucher," as we know, was the term applied by Le Grand de Saulle to subjects who felt impelled to touch certain objects; "agoraphobia" and "claustrophobia" to certain morbid fears of place, but like every other insanity with progress there is likely to be, sooner or later, a complex manifestation.

I have of late seen several cases that are rather unusual, for they implied a certain doubt of responsibility, or rather a fear upon the part of the subjects lest others should suffer from what they believed to be a constantly unperformed duty. This was the conspicuous feature of the insanity of an individual whose case I am about to relate, but it was connected with the mysophobia of Hammond, and a certain kind of repeated calculation, thus binding the third, fourth, fifth, and sixth clinical types of the insanity of doubt which appear in Ball's classification:

The patient was a man of thirty-five, presenting the stigmata of defective evolution. He was markedly dolichocephalic, his teeth were irregular, his forehead retreating, and his muscular motility impaired. His family history was essentially neurotic. His mother, after a life passed as an extreme fanatic, ended her days in a lunatic asylum. His father drank immoderately, and died in an asylum. One of his brothers was intemperate, and his sister was hysteric and neurasthenic, while one

[1] Read before the Neurological Section of the New York Academy of Medicine, October 13, 1893.

of his maternal uncles was also a drunkard. He had for several years been a prominent figure in the town in which he lived, and had devoted himself to prohibition, his enthusiasm being expressed in constant litigation and self-glorification. His entire life had been modelled upon plans laid down by social reformers whose teachings were bad, and marriage guides and books upon domestic medicine played a great part in shaping his home-life. In spite of his peculiarities, he is a successful business man, and has saved enough to live in comfort without helping his brothers, who are his partners, in the management of their business. His manner at the time of his visit was very hesitating and full of indecision. There was much hesitation in telling his story, and in answering my questions he repeated himself frequently. He fully appreciated his mental state, and suffered very great agony of mind and want of faith in himself.

His active mental unsoundness had lasted for several years, and began by a gradual fear of defilement from contamination. It was reasonable enough at first, and simply followed acts that naturally required subsequent resort to soap and water. But this increased so that he now washes his hands from thirty to forty times daily, and always does so after handling money. The impulses that compel him to calculate are shown almost entirely in business matters, although his habit is now to weigh all coin that he receives or gives out, and this he has done for the past two years. The question of the honesty of others does not seem to figure largely in this procedure, for he weighs the money which he gives to others and counts the bills several times, often following the recipient several times in the day to know whether the amount he has paid is correct. He carries scales with him, not daring to trust himself without them, and while admitting the irksomeness of his bondage, suffers intensely if he forces himself to place them beyond his reach. In his efforts to escape the imperative impulse, he often asks his brothers to take charge of his business, and he has finally been obliged to leave everything in their hands.

Some time ago his imperative conceptions took another form, which consisted in the belief that paper, pieces of tin, scraps of iron on the sidewalk, street, or elsewhere, would do injury for which he would be morally, if not legally, responsible if he did not remove them. Paper upon the road that might frighten horses, scrap-tin that might wound them, loose cobblestones and other objects, he would constantly gather and put out of harm's way. He was so dominated by his morbid fears and the possible consequences of neglect upon his part, that he refused to sell nails to his customers without removing the splints, and if the nuts upon the bolts he sold were loose he would screw them up. He would question purchasers as to the possible harm that might have occurred, and upon one occasion, when he went to Long Branch for his vacation, after an hour of anxiety and doubt upon the steamboat, he turned back at Sandy Hook, to remove a banana-skin he had passed without picking up on the sidewalk in New York.

His morbid fears were excited by any object which might do harm, matches, combustibles, and sharp tools being included, and he was finally obliged to seek new employment, taking charge of the bill-collecting part of the business. There was not in his case anything that might be regarded as a delusion. His relations with everyone, except the liquor-dealers, were pleasant. He slept well as a rule, but suffered from insomnia and disturbed digestion only when he underwent a peculiarly distressing period of doubt.

I have met with two examples of insanity which may be said to belong to this class, a description of which I have so far been unable to find. Its peculiarity consists in the fact that the subjects have a fixed but temporarily removable belief that certain parts of their bodies are larger than they should be. So marked is the mental derangement, and so clear-cut is its expression, that there is no reason why it should be confounded with either hypochondriac or well-marked delusional insanity. It is common to find sexual hypochondriacs dwelling upon their belief in an alleged atrophy of the genital organs, but we never find any complaint in regard to enlargement of any other part of their body. The declarations of the patients I have seen could not be accounted for by sensorial delusions, such as exist in sensorial Verrücktheit, because there was no difficulty in making one of them admit by reasoning that there was nothing abnormal about him. The second case, however, so closely approached actual delusional insanity, although the behavior of the patient was at first simply that of a doubting lunatic, that the case must be regarded as crossing the border-line, or approaching the extreme type of hypochondriac paranoia, for he acted upon his delusions in a very deliberate manner.

The first subject is a man of thirty-six. His father and mother had highly organized nervous temperaments, but there was no history of insanity or of intemperance in the family. He is impressionable and eccentric, although a good man of business, having charge of a large estate. He has never suffered from any special form of nervous disease, but for years he has been troubled with insomnia, and has flatulent dyspepsia. His sexual appetite has always been marked, and his fancies are extravagant. He has for many years had an idea that his hands are larger than they should be, that they are deformed, and that people are constantly noticing them. They are, in fact, of average size, not out of proportion to his height and build, and he wears a number seven-and-a-half man's glove. He rubs and feels of them constantly, compares them with those of other persons, and when riding in public places, or wherever he is likely to be the subject of observation, he hides them and eagerly watches to see whether he is the object of attention. So continually is his mind engaged in this way that he finds little pleasure in life and has practically given

up his business, and came to me after having seen many other physicians, who were unable, as I was, to reason him out of his trouble. He fully realizes the false nature of his hallucination, but is unable to antagonize the insistent idea. He has upon two or three occasions been prompted to commit suicide, because of the persistence of the mental state which he has been unable to struggle against.

The second case is one of far greater interest, because the patient has really acted upon his belief that his nose is much too large. This man consulted me about four years ago, and had been sent by his physician to see if it were possible for me to dissuade him from resorting to surgical measures which he had already arranged for. He came of nervous stock, and had all his life been eccentric and erratic, and physically showed the stigmata of a defective nervous organization. He had been known by his associates as "queer," and upon one occasion, at a picnic, had indulged in disorderly behavior and purposeless antics that were not due to alcohol, but were imperative and without meaning.

Some time before I saw him he went about among his friends, asking them whether they saw anything queer about his nose—whether it was not too large, and a number of similar questions. His friends either laughed at him or assured him of the conventional proportions of that organ, but he continued to go from one to the other, and finally sought a surgeon, who removed a piece of the septum, with some resulting reduction. However, his peace of mind and satisfaction were short lived, and he very soon insisted that the knife had done no good. He was induced to go to his own physician, who in vain tried to dissuade him from any further attempt, and advised him to see me.

There was nothing about his nose that was at all abnormal, and its proportions, while generous, were not too great, and with this idea I strove to impress him. He not only resented my advice, but took occasion to inform me that the ears of his wife were larger, he thought, than they should be, and that after the second operation he proposed having her consult the surgeon whose aid he had previously sought.

The second operation was performed, with results which were scarcely satisfactory, and I subsequently learned that though he has so far not again adopted surgical measures, he still refers to his looking very different from other people.

The subjects of doubting insanity, according to several writers, are supposed to be chiefly women, and this has been my experience so far as the mild forms are concerned, but in those examples in which the disorder has been prolonged, the majority of patients are men. It seems to be an insanity of early manhood, and I cannot recollect a case that developed after the fortieth year. It sometimes, though very rarely, begins at puberty, but when it is found at this time of life it must not be confused with the introspection of pubescence, or the expansive insanity of youth. I have seen one case, in a boy of nine, sent to me by Dr. Polk, who for nearly a year manifested a very profound *délire de toucher*, but this is the only case of the kind with which I am familiar which was presented before the eighteenth year.

Willie[1] reports the case of a girl about twelve years of age, whose insanity of doubt compelled her to minutely examine the things she ate, her trouble, later, taking the form of an unreasonable and constant fear that a window would fall upon her or upon someone else. There was an opening in the street which so disturbed her by reason of her anxiety and dread lest she or someone else should fall into it, that she pestered the police that it might be filled in. Whenever she saw matches she felt compelled to light them and to set fire to the draperies about her, although she knew the consequences of such an act and resisted.

Westphal[2] reports another youthful case, a girl of fourteen, who showed queer compelling emotions when undressing for bed. These were disorderly and explosive, and were indulged in after long hesitation and much struggle to avoid them. She was at times compelled to articulate the words "na na," and said that when she was engaged in any action she was sometimes obliged to stop precipitately, when the concept arose, and although she tried to refrain, was forced to repeat these syllables. She presented the *délire de toucher*, which afterward assumed a more insane significance, for she was compelled, according to her statement and evident sincere belief, to touch certain objects to avoid impending evil or thought. At times she would have to whisper to get rid of an unpleasant thought, and if she resisted she would become so nervous that she would scream aloud the annoying syllables.

A few months ago a boy of fourteen was sent to me by Dr. Mack, of Elizabeth, who presented a form of this disorder which I believe to be unusual, and which was due to improper religious training in a subject of defective organization. He studied hard and was ambitious, and, as a consequence, developed headaches a year ago, with indigestion and general ill-health. About two months ago his mother noticed that he washed his hands more frequently than usual, and would stand a long time before the basin in an apparently abstracted state, that he would spit in the coal-scuttle repeatedly, and that he picked up pieces of straw and matches, which were always thrown into the coal-scuttle.

He explained his actions by saying that the pieces of straw resembled crosses, and he could not show disrespect by carelessly stepping upon them. His habit of spitting, he said, was due to the fear lest

[1] Arch. f. Psych. und Nervenheilk., Bd. xii, p. 17.
[2] Quoted by Emminghaus.

the saliva in his mouth should interfere with the full effect of the communion-wine, and this was carried still further by spitting in his handkerchief. Of late he occasionally has delusions that his food is poisoned, but he denies this to me. When he crosses the railroad tracks that run near his house he is impelled to pick up stones that lie between the rails; if he does not do so he is filled with fear lest there may be a railroad accident.

He has all the distress of mind common to other sufferers from this form of trouble, if he neglects to follow his first impulses, and often returns to obey the dominant conception.

He often remains for a long time in the water-closet, sometimes for ten or fifteen minutes, and when his mother enters to find the reason of his seclusion, she discovers that he has littered the place with many pieces of discarded water-closet paper, refraining from desecrating by use any piece that contains creases that may bear any resemblance to the common symbol of Christianity. He examines each piece carefully. He sleeps very badly and has nightmares, and grinds his teeth. His pockets when examined are often found to contain various nails and sharp things that he has placed there after picking them up lest they might injure someone.

When I talked with him I found little or no intellectual disturbance, and I think he appeared to consider that his objections to his food were not so much because he thought it was poisoned, as because it might in some way interfere with his religious professions and duties; but from his mother's account he undoubtedly at other times has well-marked hallucinations and delusions.

He expressed much distress in regard to his condition, and I think to some extent realized its hold over him. Upon interrogation I found that whenever he walked in the street he carefully put out of the way or picked up any object, especially pieces of straw, wood, or paper, that in any way in their arrangement bore the least resemblance to a cross, for fear that he might commit some act of sacrilege.

After much questioning it turned out that he had received a deep mental impression from a story in a semi-religious school "reader," which was in use at the Roman Catholic school which he attended, and upon examining the book I found a highly-colored romance which had evidently been prepared for the purpose of appealing to impressible children of his particular faith.

As to treatment, it may be said that in the mild or hysteric cases it is often possible to effect a cure through improvement of the general health, but there is always the likelihood of a return. In these cases, as well as in those that fall under the second division, moral therapeutics are in order, and are sometimes very successful. It is of the utmost importance that the patient should be taught to resist not only his fears but his promptings, and he should be made to do the very things that are distasteful to him, although such a course implies some mental and physical suffering. The insanity is always aggravated by yielding, and if the physician is firm and insists upon the performance of an alleged impossible act, the patient nearly always derives relief and some peace of mind from the subsequent consciousness that he has performed it. One of my patients declared she could not ride upon the elevated railroad or cross the ferry. When made to do so several times with her nurse, she frequently undertook excursions which, of course, were not attended by unpleasant consequences.

I have with difficulty hypnotized two or three subjects, and in one case in which the disorder was a light one, obtained results that were permanent by the suggestion of a state of self-reliance.

The matter of commitment frequently arises when the patient gives a history of impulsive concepts which are likely to lead to suicidal or homicidal acts. There is no rule to be laid down in regard to this, but in well-marked doubting insanity, in which *the dominant concept has lasted for some time*, I have been reluctant to send the person to an asylum, and so far have had no reason to regret my action. A step of this kind at best is a most difficult one when the ordinary intelligence and susceptibility are so well preserved. I can recall cases that have been under observation for fifteen or sixteen years, in which the patients have upon different occasions seriously referred to their promptings to use weapons for the destruction of themselves or others, but I have been able to keep the mental equilibrium at such a point that no harm has resulted.

Of course, in cases in which the existence of genuine paranoia is strongly suggested, no risk should be taken, and the patient should be promptly protected.

The mental discipline of these patients is an all-important measure, and if some formula can be devised to enable them to regulate their mental action, an occasionally striking improvement will be the result. My associate, Dr. George De Forest Smith, has had a case of sexual doubting insanity that was improved by a suggestion that the patient should keep certain hours and certain days for decision, and it was his habit, if he had a doubt, to number it, and dismiss further speculation by a kind of procrastination, saying to himself, "I will leave No. 39 to be decided on Thursday, between 12 and 1." This action of the man led him to habits of self-control in other directions, which at least have brought about much less mental torture than existed before.

44 East Twenty-ninth Street.

THREE CASES OF LUNG-ABSCESS—WITH COMMENTS UPON THE ETIOLOGY, DIAGNOSIS, AND TREATMENT OF THE CONDITION.

BY DELANCEY ROCHESTER, M.D.,
ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF BUFFALO; ASSISTANT VISITING PHYSICIAN TO THE BUFFALO GENERAL HOSPITAL.

CASE I.—Francesco Prescope, an Italian laborer, thirty-eight years of age; married; was admitted to the Buffalo General Hospital on March 31, 1893. It was impossible to obtain any history of the case. At the time of entrance the respiration was 40, the pulse 120, the temperature 102.5° F.; the tongue was coated and the appetite poor; the examination of the urine showed normality, except some diminution in amount. Physical examination revealed over the middle lobe of the right lung, behind, and in the axilla, increased fremitus, percussion-dulness, bronchial breathing, and crepitant râles; there was expectorated the sticky, rusty sputum of lobar pneumonia. The temperature continued high, with occasional marked falls for four days, when it reached 105°; the pulse ranged from 90 to 120 during this time, and the respirations from 40 to 50. From this time on, for two weeks, there was little change in the patient's condition, except as revealed by physical examination of the chest. The dulness spread downward over the lower lobe, the fremitus, râles, and finally the bronchial breathing disappeared, but the expectoration became more purulent, and finally lost entirely the characteristics of the pneumonic sputum. Finally, on April 18th (the nineteenth day after admission) the man expectorated a large amount of purulent material. Microscopic examination of the sputum (made upon several occasions) never showed the presence of tubercle-bacilli, but at this time it did show elastic fibers. Physical examination, on April 18th, showed on percussion a tympanitic resonance on the right side in the interscapular and infrascapular regions, from the lower border of the fifth rib to the eighth intercostal space. This was easily marked out by auscultatory percussion. Below this the flatness remained. Over the area mentioned auscultation revealed amphoric breathing, amphoric voice, whispering pectoriloquy, and occasionally metallic tinkling; below this area the auscultatory sounds were still absent. The diagnosis made was lobar pneumonia followed by abscess in the middle lobe of the right lung, and probably empyema.

The man was transferred to the surgical side of the hospital for operation. The operation recommended was the removal of pieces of four or five ribs, irrigation of the lung-abscess, and packing with iodoform or zinc-oxid gauze. The operation performed was the resection of a portion of the fifth rib and drainage. After this operation the patient improved for a while; but, in spite of frequent dressings and, also, finally, a counter-opening lower down in the chest and thorough drainage, the temperature continued its diurnal rise and fall, and the patient had all the appearance of one suffering from pyemic poisoning. At length, on July 14th, the operation was completed, and one and a half inches of the sixth, seventh, and eighth ribs were removed, in addition to the section of the fifth rib that had been removed at the first operation. The abscess was irrigated and packed with zinc-oxid gauze. For twelve days thereafter the temperature varied from 98° to 101°. The man was discharged from the hospital, entirely well, September 30th. I was not notified when he was to be discharged, and so was unable to note the condition of the lung, and there is no memorandum in the surgical records as to this.

CASE II.—Refrigealo Cristeizo, an Italian, thirty-four years of age; a laborer; single; entered the Buffalo General Hospital June 8, 1893. His temperature was 101°; pulse, 130; respirations, 38. I saw him the next day and found the same rate of respiration, temperature, and pulse, the last being small and weak. Physical examination showed the right side bulging and motionless, without fremitus. On percussion, absolute flatness was found all over the right chest, in front and behind; on auscultation there were no breathing-sounds or voice-sounds. The heart was displaced to the left; there was a systolic bruit at the apex, and a diastolic bruit over the aortic valve; the pulmonary second sound was markedly accentuated. The diagnosis was pyothorax of the right side, so extensive as to cause complete compression of the lung. The dyspnea was so marked—amounting to orthopnea, the respirations rising to 44 per minute—that I advised immediate aspiration of part of the fluid to relieve this condition. Eighteen hundred cubic centimeters of cloudy, greenish, puruloid fluid were withdrawn by the aspirator, and the patient was then transferred to the surgical ward. Two days later the man was operated on by Dr. Phelps. One and one-half inches of one rib (which rib not noted) were resected, and 3000 c.c. of pus were removed and the cavity drained. At the time of this operation it was found that there was direct communication between the lung and the pleural cavity, but the extent of destruction of lung-tissue was not investigated.

After the aspiration, June 9th, the patient's general condition improved, so that on the day of the operation the temperature had reached normal, the pulse had fallen to 80, and the respirations to 30. For two days longer the condition remained about the same, but on the third day the temperature rose to 103°, falling to normal, and rising the next day to 102°, again falling to normal, and then rising to 106°. It kept on in this manner for eight days, moving from a morning record of 99° to an evening record of from 102.5° to 104.5°, the respirations at the same time ranging from 30 to 45 per minute. The temperature then ran along for five days below 101°, but still showing the marked breaks of sepsis. On the morning of July 1 the temperature was 97°, and eight hours later 104.8°—a range of nearly 8° in eight hours. From this time the temperature kept up the diurnal range from 97° to 100°, or 101°, or 102°, with a leap every third, fifth, or seventh day to 103°, 104°, or 105°. The pulse kept ranging from 100 to 140, reaching 160 some eight hours before death. The

respirations ranged most of the time from 30 to 40, occasionally rising to 50, and five hours before death reaching 80. The patient died on July 17th, thirty-six days after operation. It was impossible to procure an autopsy.

Case III.—William Croll, an American, fifteen years of age; a clerk; was admitted to the Buffalo General Hospital on September 1, 1893. Appendicitis was diagnosticated, and the patient was transferred to the surgical ward with advice for operation, which was performed on October 11th, resulting in the evacuation of a large abscess, containing 200 c.c. of thick, creamy, ill-smelling pus. The abscess extended down into the pelvis. In addition to the pus there were removed from the cavity the appendix vermiformis and a mass of new fibrous tissue, half an inch thick and three inches long. In spite of this operation, and although the local condition improved daily, the patient's general condition showed evidence of pyemia. and the temperature-curve showed the characteristic rise and fall. On October 28th the patient began expectorating bloody pus, which did not contain tubercle-bacilli. On October 30th, at Dr. Parmenter's request, I examined the patient's chest. Inspection showed diminished respiratory movement on the left side; palpation, increased fremitus in the infraclavicular and upper part of the interscapular region, absence of fremitus in the lower part of the infrascapular region, a peculiar fremitus in the lower part of the interscapular and upper part of the infrascapular region. On percussion, skodaic resonance was obtained in the infraclavicular region, slight dulness in the mammary and upper axillary region, slight dulness in the suprascapular and upper part of the interscapular region, dulness in the lower part of the interscapular region, gradually increasing until flatness was attained in the lower three-fourths of the infrascapular region.. On auscultation, exaggerated breathing was found on the right side, diminished breathing of a broncho-vesicular type over the upper part of the left lung, in front and behind, accompaned by moist râles; in the lower part of the interscapular and upper part of the infrascapular region, near the spinal column, cavernous breathing was found of peculiarly amphoric quality, changing, as the stethoscope moved downward, to distant bronchial breathing, and then ceasing altogether; egophony was also heard at the junction of the interscapular and infrascapular regions; and below this the voice sounds were absent. The diagnosis was empyema, with probable lung-abscess.

The operation took place on November 1st. From one and a half to two inches of the sixth rib were removed at the posterior axillary line, and about 800 c.c. of bloody pus evacuated. An evident opening into the lung was present, though the situation and extent of loss of lung-tissue were not investigated. The cavity was drained. The condition of the patient after operation was as follows: The temperature varied from 99° to 101°; the pulse from 90 to 100; and the respirations from 25 to 30. Physical examination on November 7th showed the presence of pus in considerable amount, and poor expansion of the lung; the opening from the lung into the pleural cavity was still present. There was poor drainage from the opening in the chest. On November 23d, the temperature had not been above 99.5° for a week, and the pulse had ranged from 80 to 90, the respirations averaging about from 25 to 30; the patient's general condition was markedly improved, the appetite good, and the bowels regular. He has gained in flesh, though very anemic, and is up and walking about the ward. Physical examination of the chest shows a tendency to droop to the left, both shoulders falling forward, and the chest being quite flat, with considerable spreading out in the hypochondriac and lower axillary regions; there is relative fulness of the left supraclavicular and infraclavicular regions, respiration rapid and shallow. Upon forced respiration fair expansion of the supraclavicular and infraclavicular regions is found on both sides, and poor expansion in the left hypochondriac and axillary regions; posteriorly there is very slight movement of the left side, with marked expansion of the right side. Fremitus is good everywhere, except in the infrascapular, axillary, and hypochondriac regions of the left side, where there is none to be felt. There is hyperresonance in the left supraclavicular and infraclavicular and suprascapular regions, slight dulness in the left interscapular and hypochondriac regions, marked dulness amounting almost to flatness in the left infrascapular and lower axillary regions, and good resonance all over the right side. On auscultation the breathing sounds are found to be good over both apices, slightly diminished in the left axillary and hypochondriac regions; posteriorly there is exaggerated breathing upon the entire right side; on the left side diminished breathing in the suprascapular, scapular, and upper part of the interscapular regions; there is bronchial breathing in the lower part of the interscapular region, and absence of breathing in the infrascapular region. Vocal resonance is diminished all over the left side in front and behind, except in the infrascapular and lower axillary regions, where there is none.

As to the heart, the apex is in normal position, the action weak and hurried, the first sound relatively weak, the pulmonary second sound accentuated; the wound in the side is closed, but is not skinned over, there being present an exuberant growth of granulation-tissue.

Of these three cases, the first was proved to be one of pulmonary abscess, and is of special interest from an etiologic point of view, as it was a definite case of lobar pneumonia terminating in abscess and final recovery. Of this condition Fagge says: "The formation of an abscess in the lung-tissue as the result of true pneumonia is admitted by all writers to be very rare. So far as my own observations have gone I am quite disposed to agree with those who doubt whether it ever occurs."

Of abscess of the lung following lobar pneumonia, Flint says: "The collection of pus in an abscess leads to a sudden and copious purulent expectoration, if the life of the patient be sufficiently pro-

longed, and the existence of a cavity may be determinable by physical signs. This is a grave event, but it by no means necessarily renders the disease fatal. It occurred in four out of one hundred and thirty-three cases which I recorded and analyzed, and two of these four cases ended in recovery."

Osler says: "Abscess may result from purulent infiltration of lung-tissue. It occurred in four of my one hundred cases (autopsies). Usually the lung breaks in limited areas, and the abscesses are not large, but they may involve a considerable portion of a lobe."

As regards etiology Osler says: "Suppuration occurs in the lung under the following conditions: 1. As a sequence of inflammation, either lobar or lobular; after lobar pneumonia it is extremely rare; on the other hand abscess-formation is extremely frequent in the deglutition and aspiration forms of lobular pneumonia." (Possibly our second case may have had some such origin.) "2. Embolic, so-called metastatic abscesses, the result of infectious emboli, are extremely common in a large proportion of all cases of pyemia." (Our third case was undoubtedly one of this class.) "3. Perforation of lung from without, whether from external injury or perforation of abscess from below. 4. Tuberculosis."

The diagnosis of abscess of the lung is not difficult if one bear in mind the etiology, and follow closely the clinical developments of his cases.

In any case of lobar pneumonia which does not run a typical course, the possibility of termination in abscess should be borne in mind, and its development watched for. Septic fever, change in the character of the sputum to pus or bloody pus, rapid or sudden increase in amount of the sputum, and the physical signs of cavity, indicate lung-abscess. In the physical exploration of the chest I wish to lay especial stress upon auscultatory percussion as a most important procedure in the diagnosis of the existence and the extent of the abscess.

In all cases of empyema the possibility of the coexistence of lung-abscess should be borne in mind and the condition looked for. My third case illustrates this condition. Which was primary in this case it is absolutely impossible to say, but there is greater probability of an abscess breaking from the lung into the pleural cavity than from the pleural cavity into the lung, although the latter event does sometimes occur. In all cases of suppurative disease in any part of the body the supervention of respiratory difficulty should call for immediate examination of the thorax; even when there is no apparent respiratory disturbance in such a case, the continuance of the febrile symptoms after the evacuation of pus from the original seat of disease should call for a rigid examination of the entire body, including a careful physical examination of the chest to determine, if possible, the situation of any collection of pus. Having determined the existence of an abscess in the lung, the matter of treatment next confronts us. It is possible that certain cases may recover after evacuation of the abscess spontaneously through a bronchus (I believe the two recoveries mentioned by Flint occurred in that way), but by far the best practice is to open through the chest-wall into the pleural cavity, and thence into the lung, if the opening from the lung into the pleural cavity has not already occurred spontaneously. The opening into the chest-wall should be made sufficiently large to allow the extent of injury to the lung-tissue to be discovered, and to allow of thorough irrigation of the abscess-cavity and of the pleural cavity; then the abscess should be packed with zinc-oxid gauze or with iodoform-gauze and zinc-oxid gauze, the dressing to be changed as frequently as necessary. I think if the primary operation in the first case reported had been as thorough as it afterward had to be made, the second and third operations would not have been needed, and the case would have recovered much more quickly. I think that if the operation in the second case had been as thorough as indicated, the patient would probably have recovered, for he lived for a month after the imperfect operation. The result in the third case shows either that the opening from the lung into the pleural cavity was very small, or that occasionally a case of lung-abscess may recover after simple drainage. However, even in this case the present condition of the left chest, as shown by physical examination, is one in which the lower part of the pleural cavity has become so filled with granulation-tissue that the lung cannot expand there. It seems to me that there would have been greater probability of healing, with less granulation-tissue, if the original operation had been extensive enough to allow thorough drainage and antiseptic treatment of the interior of the abscess.

The *rationale* for a thorough operation in cases in which there is an opening present between the lung and the pleural cavity is this: By removal of the fluid from within and around the lung the capillaries of the lung are opened up and their absorptive power rendered most active; if now the external opening is not sufficiently large to allow thorough drainage to take place, and the parts are not rendered clean by irrigation, the absorption of septic material into the circulation must be extensive and the patient's condition rendered really worse than before operation; if, however, a sufficiently large opening is made and thorough drainage established, the abscess-cavity can be rendered as nearly aseptic as possible by packing with anti-

septic gauze, and thus the patient's chance for recovery is made immeasurably better.

These statements are thoroughly borne out by the course of the first case cited. The first operation was the removal of a part of one rib and the establishment of poor drainage; the septic condition continued and grew worse; the second operation was the making of a counter-opening lower down in the chest, with irrigation and the establishment of thorough drainage of the pleural cavity; the patient's condition was slightly improved for a time, but septic poisoning returned with great vigor; the third operation was the removal of pieces of four ribs, thorough irrigation, and aseptic packing of the lung-abscess, and the result was recovery.

The special point that I wish, particularly to emphasize is that in all cases of empyema in which an opening from the lung into the pleural cavity is present, enough of the chest-wall should be removed to enable the operator to investigate thoroughly the nature of the opening and learn the amount of destruction of lung-tissue. In this way if it prove to be an abscess, it may be treated as an abscess should be treated in whatever part of the body it may occur.

THE INCISION IN ABDOMINAL SECTION: HOW TO CLOSE IT, AND ITS POST-OPERATIVE COMPLICATIONS.

By JOSEPH PRICE, M.D.,
OF PHILADELPHIA;
PHYSICIAN-IN-CHARGE, PRESTON RETREAT; PHYSICIAN-IN-CHARGE, FEMALE DEPARTMENT PHILADELPHIA DISPENSARY.

The question that most vitally concerns us in our surgical and gynecologic work is: How can we reduce the mortality? The question is a momentous one, when it is considered that it is human life we deal with; that our surgical judgment and surgical fingers repeatedly determine the issue of life or death. Our progress, the victories gained, are gratifying but not satisfying. We go back only for the lessons of skilled experience, to get in more intimate touch with the teachings of those who blazed the way for us against the superstitions and prejudices of ignorance. It was not within the human limits of the honored pioneers of our profession to drive out all the darkness and let in all the light, nor will it be within ours.

While the ignorant mob may not be at our doors clamoring for blood in atonement for our real or imagined failures, there is a malign power still not broken, throned about educational centers, scattered everywhere, and to our humiliation finding mischievous allies in the ignorant, prejudiced, and unscrupulous of the profession. They are the men who embarrass advanced teaching, who place in the way of the progressive, conscientious, and practical teachers their chief obstruction and discouragement. The man who cannot or will not learn should practise at least the virtue of silence. Not a few of the afflicted suffer premature death, or live useless lives, live through years of avoidable suffering, through ignorant and pernicious intermeddling.

We refer to our surgical advances as marvellous. In a strictly modern sense they have been so, yet half a century elapses between McDowell, Bernham, and Mr. Tait. The Atlees, with their sound surgical judgment, their masterly surgical skill, and their high professional honor, come in early and make profitable history for the surgeon's reading. With our better perfected methods we are fortunate in the possession of the advantages of the lessons the wisdom and courage of these men evolved and mastered. A glance at our own field faintly conveys to us some realization of the embarrassments with which they contended. They did that which made it possible for us to be where we are: they made an intelligent beginning. We cherish the faith that they transmitted, to men of our own day and generation, some of the mettle which gave them their triumphs.

Let us begin where our surgery begins—with the incision. We have nothing from which we can even approximately determine to what extent the length of the incision influences the mortality. The statistics of comparative results would not prove satisfactory for the reason of the entry of so many other compromising elements—for example, adhesions, their character, extent, and locality. That the length of the incision exercises a greater influence than is generally recognized or admitted, I entertain little doubt.

As to length, no rule of mathematic certainty can be laid down. In my own experience I find the balance of both convenience and safety to lie with the short incision. Muscle undamaged and intact is the material and best protection to the abdomen, and there is less bleeding when it is uncut. A short incision narrows the limits of hemorrhage. However simple may be the structures composing the abdominal walls, a lengthy incision gives unnecessary extent to exposure of the peritoneal cavity and the abdominal viscera to atmospheric influence, and to needless contact with the hands of the operator—and this without lessening the difficulty in dealing with those varying emergencies constantly encountered by operators. It is safe to begin with a small incision, and when the size and character of the tumor or complications present require a longer one, it can easily be made. Very much of our abdominal work can be done through an opening admitting only two fingers. The reliance of the abdominal surgeon must be largely in educated fingers. Diseased tissues may be dealt

with through a small incision; exposure of adhesions to view is not necessary, except those of the small bowel. In a majority of cases an operation can be done through a small incision without the operator or spectators seeing the viscera. Universally adherent, irreducible, or solid tumors, require a long incision for delivery, and for dealing with complications that can only be dealt with through the long incision—those beneath and on the sides of tumors. In the majority of cases to so enlarge the opening as to obtain a view of the parts augments the risk of ventral hernia and provokes tedious convalescence.

The question as to the length of the incision continues a controverted one, and the opinions of those who by reason of their experience are entitled to speak with some weight of authority, have for us a practical interest, though we may not accept them for our guidance. Peaslee, in his excellent work on ovarian tumors, in referring to the controversy that arose in England between the advocates of the long incision and those of the short one, says: "It is sufficient for my purpose to state that by the short incision I mean one from three to six inches long, and by the long incision one of ten inches or more, and sometimes extending from the symphysis pubis to the ensiform cartilage, as practised by Dr. Charles Clay." Quoting Kœberle, he says: "In his first 69 cases the mortality was directly proportional to the length of the incision. He found that of 12 cases in which the incision was from two to four inches, only one died; of 48 cases, with a length of from four to ten inches, 15 (one-third) died, and if the incision was from ten to sixteen inches, 8 out of 22 died." But Kœberle, unlike Dr. Clay, adopted the long incision only when obliged to do so. In his first case of ovariotomy Dr. McDowell made an incision nine inches long. He said of his operations: "My incisions were always so free and extensive that I always performed every part by sight." Dr. Nathan Smith in his first ovariotomy (1821) made an incision three inches long and successfully removed an ovarian cyst through the incision. The early advocates of the short incision regarded all incisions as short that did not exceed six inches. Peaslee lays down the following practical rules:

"1. To make the opening into the peritoneal cavity for the removal of the tumor at least three inches long to begin with, and, of course, longer in case of large cysts which cannot be essentially diminished by tapping; and

"2. Then to prolong it, if necessary, and only so far as is actually required."

He illustrates as follows what is meant by long and short incisions, and, in his view, their relative dangers: "Making the distinction of (1) very short incision, two and a half inches and less—and such alone was really meant by the operatio minor; (2) short, three to six inches; (3) long, six to ten inches; and (4) very long, ten inches or more—operatio major." Their relative danger may be pressed as follows:

Very dangerous.	Less dangerous.	Comparatively safe.	Very safe.
Very short, two and a half inches or less.	Very long, over ten inches.	Long, six to ten inches.	Short, three to six inches.

The bad results of German ovariotomists, when they have been bad, cannot be logically or justly credited to the short incision; when they have failed, their failures are to be credited to other causes, chiefly to dirt. Their recent work has been good.

I repeat that my own experience does not accord with the experience of the advocates of the long incision. I cannot, therefore, accept the opinion that a short incision is dangerous. Through a small incision—except in cases of large, irreducible, or solid tumors, of course—there can easily be conducted all needed manipulation of parts, thorough explorations for adhesions and their safe detachment, and a careful cleansing and flushing of the peritoneal cavity.

When the one idea, that of safety, dominates all others, every precaution will be used to prevent accident in any form. The importance of a perfect closure of the incision has only recently received the attention that it deserves. The effort should be to approximate as nearly as possible normal conditions, anticipating and dealing with all existing or possible complications with scrupulous minuteness and care, thus guarding against those accidents that are too frequent. It is true that some of our bad results are beyond our explaining and beyond our avoidance, but there are many accidents for which we have no valid excuse. In the major number of our cases we can account for the accidents from which our patients suffer and with which we have to deal; we can trace the trouble very generally to the manner in which the operation was done—to bad, incomplete, or too much surgery.

For a long time the closure of the incision was a matter of rude surgery; transfixion-pins, with figure-of-eight strings thrown about them, constituted a common method. I do not pretend to suggest uniform procedures for all cases; each operator has his own way, and does his own work best in that way, and without special training it would not be possible for him to apply the methods of others safely and successfully. I am satisfied that the exposure and manipulation of the incision, as well as

the peritoneum, is harmful. Incisions bathed in pus and filth, and freely manipulated, often refuse to unite. The incision is an outward, a surface sign of our workmanship, and we should have some pride in its character; it should not be a sign of mutilation. An extensive incision, one indicating careless, slouchy, indifferent surgery, is something more than a discredit to the surgeon; it is a continuous annoyance to the patient.

Careful study and effort should be made to avoid the presence of cicatricial tissue. Strenuous endeavor should be made to secure primary union in all wounds. Suppurating wounds are largely due to careless closure or to tight sutures including too much tissue; tight suturing is too common, and in many feeble subjects has destroyed life. Suppuration due to tight suturing and stitch-hole abscesses in all sections prolong convalescence when they do not result fatally.

The now-fashionable buried suture is not free from danger; nor is this method carried out by any material giving the perfect result claimed for it. In two cases I have repeated operations on the same patient to remove the entire scar. These two patients came to me with scars studded all over with sinuses; in one I feared sarcoma of the scar, but, after removing the large diamond-shaped piece underlying the entire width and length of the scar, I found upon careful dissection numerous ligatures or buried sutures throughout its entire center. Through the many years of suture-experiment the application of the buried suture at any and all points of the body has been found a failure. The use of the silver ligature in ovariotomy has been followed by abscess and death. The buried suture in the female perineum is also followed by suppuration. Human tissues will not tolerate the presence of a non-absorbable foreign body. Undue chances and liberties should not be taken with the peritoneum because of its great tolerance.

That eminent old English surgeon and author, Richard Wiseman, as far back as the reign of Charles II, more than two centuries ago, wrote, under the caption of "Wounds of the Belly": "Authors have proposed several ways of stitching these wounds which I shall not trouble you with, but advise you to make your stitches deep, that the peritoneum may be united with the flesh; for if you fail therein a hernia must necessarily succeed." Through-and-through suturing, including all structures, more of the central structure than skin or peritoneum, with either silkworm-gut or pure silk, two of the strongest and cleanest of all materials known, have given and continue to give the most satisfactory results. Silkworm-gut seems to be the favorite material at present; it possesses all the natural and essential qualities of a suture, is small, strong, and non-irritating—the three cardinal virtues of all good suturing material. The method of terracing sutures has nothing to recommend it, while it prolongs the operation, which is an important consideration in all cases in the hands of young operators, who under the stress of the occasion are likely to forget the results of a careless and needlessly prolonged anesthesia. Retraction of skin and peritoneum by the introduction of silkworm sutures gives inclusion of more central structures and the least possible tension on skin and peritoneum.

To so introduce sutures as to secure the desired results requires practice with a fine, straight needle and the education of the fingers. By such methods it is exceptional to have cutting sutures or stitch-hole abscesses. In tying the sutures you will find muscle and aponeurotic structures in apposition before the skin approximates. Keith, Tait, and Bantock all use the fine, straight needle; their work has been about perfect. The use of large curved cutting needles is harmful, as they favor hemorrhage and, secondarily, stitch-hole abscesses. In anemic patients the Hagedorn needle favors hemorrhage; it has a cutting edge of quite one line in length. Too much emphasis cannot be placed upon the use of silkworm-gut sutures, introduced three or four to the inch, including all the structures of the abdominal wall. The use of uncertain material like catgut or tendon is a mistake, as, if one rely upon the manufacturer, he is never certain of its purity or quality. The surgeon should cleanse and prepare his own materials if he would do good work.

To minimize post-operative complications and the discomfort of the patient all operations should be done rapidly, through the smallest possible incision. Existing adhesions, omental and bowel, should be freed, the finest and purest of silk and the least quantity consistent with safety should be used; heavy, coarse material, silk or other, should not be used. Viscera should be placed in normal position and the incision closed after careful drying. Dry dressing with a snugly-fitting bandage is sufficient. I have given all methods of suturing the abdominal wall a faithful trial. I have also watched the methods and results of others, and again in re-operations in removing scars I have made careful studies, that I might determine the best. The deductions of my experience confirm me in the use of the methods and material I have suggested.

The operation of hysterectomy differs from ovariotomy in requiring a very much larger incision, because the tumor is solid. Mr. Keith says:

"I do not think that the length of the incision influences much, if it influences at all, the result in hysterectomy. The closing of the large wound prolongs the operation, but the after-comfort of the patient is in no

way affected by the length of the incision, if proper care be taken at the time to close the wound very accurately by a sufficient number of deep sutures. Of these I put in about four to the inch. Where the wall is thin, as it generally is, about the umbilicus a larger number may be required. I have put in a great number of sutures, and I think I put in twice as many as anyone else, and take in the whole deep tissues of the wall. I have seldom had to see a patient on account of any discomfort arising from the wound. There is no greater mistake than to include only the skin and peritoneum (this is Spencer Wells's method). It saves trouble at the time, perhaps, but in a month or two the patient suffers. It is said that the cicatrix comes to this in the end in all cases. It does not; with a properly united wound, with a sufficient number of deep sutures, taking in all the tissue, no hernia ought to happen."

Dr. John Homans, of Boston, in his little book reporting his work, says:

"The usual length of my incision is about two inches, except in fat people, or when some difficulty in the operation requires more room. I have always used silk sutures, and am careful to include all the abdominal parietes in the suture, particularly the tranversalis fascia."

To the following recommendation by the same author we most decidedly object: "During convalescence the patients have found the lifting-machine, figured in Hamilton's surgery as Dr. Jenks's fracture-bed, very useful, portable, light, and strong." I object to whatever involves the risk of strain upon the muscles. Strain is one of the chief causes of hernia. Machines strain, and when they are used no one need be "surprised to find that 30 women out of over 300, or nearly 10 per cent., have ventral hernia."

The old principle of rest, position, and pressure is as valuable in special as it is in general surgery. By rest I mean absolute lying on the back for days, limited only by the necessities of the case—the condition of the patient. For the first day it may seem irksome, but the patient, under kind and attentive nursing, soon rallies from this sense of irksomeness. Patients turned early, as a rule, do badly, and their incisions often give trouble.

DIPHTHERIA: PRIMARILY A LOCAL, SECONDARILY A CONSTITUTIONAL DISEASE.

BY W. CARROLL CHAPMAN, M.D.,
OF LOUISVILLE, KY.

PEPPER, 1893, says: "The majority of authors are still agreed in calling diphtheria a general or constitutional disease which develops a local lesion at some period of its course, though many are inclined to advance the opinion that in *exceptional* cases the local lesion may first appear."

Yeo, 1893, says: "It has been established that it (diphtheria) is primarily a local disease, a local infection, and that the constitution is secondarily affected by the absorption of toxic substances developed by the activities of a specific micro-organism at the seat of local infection."

Microscopy has been the principal means of real advancement in this subject, but there are more ways than one to arrive at a positive conclusion in the majority of cases. As an illustration we might allude to a case in which syphilis is suspected, the history obscure, the initial lesion not well marked, and the eruption so slight as not to have been noticed, and yet, later, symptoms manifest themselves of a serious character, which quickly yield to syphilitic treatment and to no other. In such a case we are justified in a diagnosis of syphilis.

By the same manner of reasoning we are sustained in the conclusion that diphtheria is primarily a local and secondarily a constitutional disease. In support of this claim I will briefly relate the following nine cases and the *treatment* or *not* of the *other* children in the families exposed.

FAMILY NO. 1; CASE I.—On November 22, 1892, I saw V. S., ten years of age, whose tonsils had been enlarged since infancy. I found the pharynx and tonsils inflamed and tumefied; the temperature 104°, the pulse 120, and the cervical glands enlarged. I pronounced the case one of tonsillitis, and ordered treatment accordingly. On the third day the symptoms were not being allayed and the child was in a stupor, with mouth-breathing. Inspection was made, and a diphtheric membrane was noticed on the tonsils and muscles of the pharynx. The membrane was well marked, as was also the peculiar musty and fetid odor of diphtheria. I immediately placed the patient on potassium chlorate, tr. ferri chloridi, and stimulants; I also used a spray of hydrogen dioxid and water, equal parts, in the throat and nose. The other rooms of the house were thoroughly fumigated with sulfur, and the two other children were separated from the patient. Communication between parents and children could not be prevented.

On the fourth day the temperature was 102°, the pulse 110, with complete obstruction in both nostrils, and in them membrane plainly visible. The foregoing treatment was continued for five weeks, except that as the case improved the H_2O_2 was diluted by four or five parts of water. The temperature ranged from 100.5° to 102° until convalescence became established.

CASE II.—Four days after the appearance of membrane (seventh day of disease) in Case I, a sister, aged eight years, was taken with an inflammation of the pharynx and tonsils. The temperature was 104°, the pulse 120. On the second day whitish patches made their appearance, which on the third day developed into the diphtheric membrane with all the symptoms of diphtheria—mouth-breathing, enlargement of cervical glands, fetid odor, and stupor—the membrane in this case also reaching into the entire nasal cavity. On the first appearance of the disease the same treatment was begun as in Case I—potassium, iron, whiskey, and antiseptic spray—and continued to convalescence.

Case III.—The youngest sister, aged six years, was taken with the same symptoms on the sixth day after the appearance of the membrane in Case I. The disease developed and was treated in the same way as in Cases I and II, to convalescence. Each child was treated, from the time of the commencement to dismissal, for about seven or eight weeks. All recovered, the symptoms never becoming graver than those of the first three days after the appearance of the membrane, except a sinking spell in the youngest about the fifteenth day. This was treated by increase in stimulants, the patient rallying in about eighteen hours.

Family No. 2; Case IV.—October 21, 1893, J. W., aged eleven years, had been sick for three or four days when I was called. Examination of the throat revealed diphtheric membrane. The temperature was 103°; the pulse 108; there were present cervical enlargement and all other symptoms of diphtheria. I fumigated the house with sulfur and excluded the other children from the patient's room. The same treatment was employed, except the whiskey, as in the three cases already narrated.

Case V.—Four days later the younger brother, aged four years, was taken ill with the disease. The same treatment was carried out.

Case VI.—Two days later, or six days after the first case in Family No. 2, the next oldest boy contracted the disease. In Cases IV and VI the membrane formed in the nose also; in Case V it did not. The baby, nine months old, escaped. The disease was light, lasting only thirteen, ten, and fourteen days respectively. The same treatment was used.

Family No. 3; Case VII.—A. S., four years of age, was taken ill October 25, 1893. The temperature was 104°, the pulse 126, the pharynx red; there was stupor, cervical enlargement, and vomiting. I gave a cathartic with bismuth and carbolic acid. On the third day white patches appeared in the pharynx, which developed into well marked diphtheric membrane on the fourth day, with all the symptoms of diphtheria. I fumigated the house, and separated the child from the other two children, and with a second atomizer had their throats and noses sprayed twice daily with the same antiseptic, diluted with five parts of water. They escaped the disease, although Case VII was well marked. The same treatment was used as in the other cases reported, extending over a period of twenty-one days, with recovery.

Family No. 4; Case VIII.—V. G., ten years of age, was taken ill on October 30, 1893. She had been sick four days when I was called in. The diphtheric membrane was well developed in the nose and throat, as were all the symptoms of the disease. The temperature was 103°, the pulse 120. Iron, potassium, stimulants and the antiseptic spray were ordered. On the second day, the fifth of the disease, the temperature was 98°, the pulse 100 and feeble. I increased the stimulants. There were nausea and vomiting. The temperature ranged from 97.5° to 100° until the thirteenth day, when the child became worse, the temperature 97.5°, the pulse 140 and feeble. I then gave digitalis. The membrane had now about cleared away; the child rallied for a few hours and died suddenly from heart-failure. The brother, two and one-half years old, was permitted to be in the same room all through the illness, but his throat was sprayed with a solution of H_2O_2, 1 to 5, daily, without symptoms of the disease arising.

Family No. 5; Case IX.—M. M., six years of age, on November 12, 1893, had been sick four days when I was called. I found diphtheric patches appearing, and the patient almost completely overcome by the intensity of the poison. I ordered stimulants, iron, potassium, and the spray. On the second day the membrane was well developed, but the symptoms were allayed, and continued so until the twelfth day of the disease, when the spray was left off and the patient became worse. The spray was recommenced, with alleviation of the symptoms, and was continued to convalescence.

Here we have nine well-marked cases of diphtheria, with one death—a mortality of about 11 per cent. Before using this treatment, with especial attention to the spray, I am ashamed to say the mortality of my cases was about 75 per cent., although I had used the potassium, iron, and stimulants, with other local applications mentioned, brushed or blown on the surface.

The result of the observations upon these cases points to the following conclusions:

1. Diphtheria is manifested locally first, the disease being often overlooked until the constitutional symptoms appear, these being caused by the absorption into the system of the toxic albumin given off by the Klebs-Loeffler bacillus.

2. The bacilli forming the toxic albumin are located in the larynx, pharynx, or nose, because the symptoms of poisoning by them are allayed when the proper germicide is thoroughly applied to these mucous membranes.

3. Even if the bacilli are situated beneath the surface, a solution of H_2O_2, and probably of other antiseptics, has the power of reaching them.

4. Constitutional symptoms appear to be prevented when the germicide is applied, at intervals of two hours, before absorption or secretion of the toxic albumin has taken place.

5. It seems clearly proved that the bacillus first attacks, at least in a large majority of cases, the membrane of the throat and nose exclusively, as those children exposed to the disease but whose noses and throats were treated with germicide daily during exposure, did not contract the disease, while those not so treated, except in one instance, did contract it.

6. Hydrogen dioxid, and probably mercuric chlorid, and some other germicides, in proper solution, have the power, when applied to the bacilli, to render them inactive and probably to destroy them, thus preventing secretion of the toxic albumin.

In support of this claim attention is called to Case IX. When the spray was left off on the twelfth day, at a time when the membrane had not entirely left the post-nasal space, there was a reappearance of the toxic symptoms. It might also be well to state that in Case VIII the atomizer broke ten or twelve hours before death and the spray was not introduced well. In several cases now under my observation, with the same treatment, the same results are being obtained.

The number of cases here detailed may be too small to definitely prove the conclusions drawn, but they strongly support the position taken, and further observations in this line will likely establish the fact.

A NEW METHOD OF TREATMENT OF CHRONIC NASO-PHARYNGEAL CATARRH.

BY W. H. BATES, M.D.,
ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY.

SEVERAL years ago, after relieving a number of patients of dacryo-cystitis by syringing the sac and nasal duct, the patients stated that they were also relieved of their chronic naso-pharyngeal catarrh. This fact suggested investigation, and patients without symptoms of disease of the tear-passage who had naso-pharyngeal catarrh were treated by syringing this passage. More than fifty patients have been thus treated with benefit during the last two years. The following two cases were typical and received no other treatment.

CASE I.—Mr. R., forty-one years of age, began treatment October 16, 1891. He had had chronic naso-pharyngeal catarrh for twenty years. There was considerable hypertrophy of the turbinated bodies. Nasal breathing was obstructed on the right side more than on the left. He had been treated by the galvano-cautery, by sprays, and by removal of pieces from the nose, with only partial and temporary relief. He was under the care of one physician for fifteen years. The sole treatment I employed consisted in syringing sweet oil down the nasal duct three times a week. At the end of four months the patient stated that his nose felt freer than ever before. He could breathe as well through the right side of the nose as through the left, and there was no discharge of mucus. The patient did not take cold as he formerly always did.

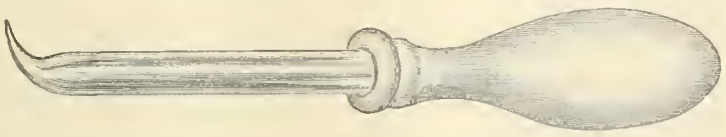
On October 15, 1893, more than a year after stopping treatment, the patient states that the relief has continued. He seems cured.

CASE II.—Mr. M., forty years of age, began treatment March 14, 1892. He had been a great sufferer from chronic naso-pharyngeal catarrh as long as he could remember. The mucus in his throat was profuse, thick, tenacious, and much worse in the morning. Efforts to clear his throat in the morning as a rule excited nausea and vomiting, so much so that he had never been able to eat any breakfast. He had hypertrophy of the turbinated bones, the right side being much worse than the left. For a number of years he had had hemorrhages from the right side of the nose, occurring at least twice a week, and lasting from two to eight hours. He was also a great sufferer from headaches, which were aggravated by frequent "colds" in the head. Ten years ago he was treated by cleansing and astringent sprays, and obtained some relief, which was only temporary.

Syringing the tear-passages with solutions of salt and water and nitrate of silver, gr. j to ℥j, gave some relief. Syringing the tear-passages with sweet oil gave greater relief, and treatment three times a week for three months was followed by apparent cure.

On October 1, 1893, more than twelve months after cessation of the treatment, the patient stated that he still felt relieved, and he has had no hemorrhages from the nose. Both sides of the nose seem clear. There is no mucus in the throat. He has not been troubled with nausea or vomiting. For the first time in his life he has enjoyed his breakfast every morning. The headaches have not returned, and he has had no colds in his head.

The syringe used is the ordinary glass eye-dropper with the tip drawn out to a fine point, and is made by Messrs. Kellogg & Co., of New York. The tip is bent at an angle of nearly 90°, and is about one-fourth of an inch long. The opening is so small that the rubber bulb fills with air in about half a second after removal of the pressure of the fingers.



To fill the syringe with water requires about five seconds, and to fill the syringe with oil may require several minutes. The tip is small enough to enter the smallest punctum, and tapers so abruptly that it closes the largest punctum, thus preventing a return flow of fluid. The syringe with its rubber bulb is about three inches long. A glass syringe is much lighter and cheaper than one of metal. Besides, with the glass syringe one can tell whether the injection is effective by observing the column of liquid. A syringe made with a glass barrel and metallic tip proved heavy and otherwise objectionable.

Care of the syringe is important. The point breaks very easily. A box should be prepared with a bed of soft cloth. The syringe should be placed in the box lengthwise and covered with a thick layer of cloth. Cotton gets into the opening of the

syringe and stops it up, but may be washed out with water. After using the syringe it should be returned to its case to prevent breakage.

Of the remedies used, olive-oil gave the most general satisfaction. Nitrate of silver was used in aqueous solution, from gr. v to gr. xx to ℥j. A saturated solution was used in several cases without injury. Menthol ʒj, olive-oil ℥j, proved beneficial in some of the cases. This combination required extra care to keep the fumes out of the eye. Weak solutions of iodin seemed to act well in some of the cases. They seemed, however, to irritate after being used a number of times. Salt and water were used with temporary benefit in some cases. Solutions of alum, copper, and zinc were used without much benefit. Solutions of mercuric chlorid were not beneficial, and diluted camphorated oil was used without much relief.

To make the injection the operator sits in front of the patient. Artificial light from an Argand burner is reflected by the forehead-mirror on the inner side of the eye, direct illumination being less satisfactory. The operator may also stand behind the patient, who is then directed to look upward and outward. A piece of cotton about one-fourth of an inch in diameter is placed over the semilunar fold and held with the forefinger of the left hand with slight pressure against the upper punctum; this prevents the fluid from entering the eye from the punctum of the upper lid. The thumb of the left hand everts the lower lid sufficiently to expose the punctum. The syringe, partly filled with the fluid to be injected, is lightly held by the bulb with the thumb and first two fingers of the right hand, the tip is inserted into the punctum and the syringe turned until the tip is at a right angle to the margin of the lid and parallel to the conjunctival surface of the lower lid. Slight pressure is made on the bulb, and the level of the fluid in the syringe is seen to descend as the injection is being made. When the injection is finished, and as the syringe is removed, press the cotton with the left forefinger against the lower punctum to absorb any overflow of the fluid. The injection can be made with the eye closed. Some cases do not require the upper punctum to be closed.

Among the difficulties noted are the fact that the punctum may be so small that the tip of the syringe does not enter readily. Dilatation with a pin remedies this. It is seldom necessary to enlarge the punctum with a knife. Sometimes the injection is difficult after the tip is introduced into the punctum, and manipulation of the syringe up, down, and in various directions will be required to free the point from the obstructing conjunctival fold. Nervous patients give trouble, and in such cocain helps, but does not always relieve, the difficulty.

More than five thousand injections of sweet oil were made without injury to the patients. Injections of other solutions at times seemed injurious. The glass syringe never broke or caused trouble during the injection.

The immediate effect of an injection of sweet oil down the nasal duct was to open the nasal passages. Many of the patients stated that the oil "opened the nose and head" more than anything previously used, and were concerned lest the air entering so freely the cavities of the head might be injurious. No case was so bad or had lasted so long a time but that the oil made the passages feel more free. The effect of the oil was to immediately lessen pain in the head, whether frontal, occipital, or temporal. In a case of spinal sclerosis with severe headache and shooting pains in the ears, the pain was completely relieved by syringing the tear-passages with sweet oil. The accumulation of mucus in cases of hypertrophic rhinitis is loosened at once, and can be removed by blowing the nose. In atrophic rhinitis no immediate benefit is noticed. The discharge is lessened in hypertrophic rhinitis, and may be entirely relieved. In atrophic rhinitis there is benefit, but the benefit is not so marked.

The beneficial results were not due to antisepsis. The oil did not act as an astringent; nor did it cleanse the nose. Its action must be explained through the nervous system. Ointments and oils relieve congestion of the skin and thickening of the skin; and oil in the nasal duct may by osmosis penetrate to the sinuses of the head, and, by its emollient or soothing effects on the nasal nerves, relieve congestion or hypertrophy of the mucous membrane.

64 East Fifty-eighth Street.

THE MANAGEMENT OF THE EPICYSTIC FISTULA IN PROSTATIC ENLARGEMENT.[1]

By JOHN D. S. DAVIS, M.D.,
of Birmingham, Ala.

Epicystic surgical fistula is the title given to a suprapubic fistula into the bladder created by the surgeon for exploration, intra-vesical treatment, and drainage. Such a fistula, acting as an artificial urethra, is capable of giving free access to the interior of the bladder for cystoscopic exploration, to provide a ready, convenient, and comfortable means of emptying the bladder at will, and gives the surgeon a competent opening into the viscus for intra-vesical applications. It constitutes an essential element in the speedy and complete evacuation of the contents of the bladder in all epicystic operations, and imitates Nature in the restoration of its own

[1] Read before the Southern Surgical and Gynecological Association, November, 1893.

continuity as the pathologic changes within the bladder subside. Permanent after-drainage in all intra-vesical operations cannot be necessary, but it is highly essential to secure good and sufficient drainage until the paracystic tissue is disengorged, the cystitis relieved, the urine normal and passing by the urethra unobstructed. Until this end is attained complete artificial provision for the escape of the contents of the viscus must be made. In cases of prostatic hypertrophy or malignant growths, when removal of the obstruction is impossible or contra-indicated, the epicystic surgical fistula is clearly indicated and essentially necessary.

When Dr. McGuire suggested his coffee-spout fistula for the relief of enlarged prostate, the idea struck me as unique and desirable; but before I had succeeded in establishing my first fistula after his method I found that practically it was not a success. In the first case in which I tried to create this kind of a fistula I found that I could not keep it in order. Finally, an abscess formed and opened on the pubic side, which allowed the urine to escape in a direct line, and I could never completely close the abscess-fistula or make the urine return to the original coffee-spout fistula. And, after many attempts at closure of the abscess or direct fistula, I finally made a plug or stem for the fistula resulting from the abscess, and allowed the original fistula to close. My experience with several cases operated upon with the view of creating a fistula after the method of Dr. McGuire convinced me that it was exceedingly difficult to create a coffee-spout fistula. I therefore began operating with the view of creating a direct fistula into the bladder, which I have heretofore described, by three methods:

1. When the distention is great and no intra-vesical operation is necessary, the opening is made with a trocar, withdrawing the stylet and replacing it with a rubber catheter, after the introduction of which the canula is withdrawn, leaving the catheter in the bladder. It is better to have the canula in place about twenty-four hours before introducing the catheter alone.

2. When distended the bladder may be opened by a direct incision with the knife in the median line, with the cutting edge toward the symphysis pubis. The knife is withdrawn and a catheter is introduced through the wound in the bladder.

3. A perpendicular incision, one or two inches long, is made in the median line above the symphysis pubis; the recti muscles are separated to the symphysis, and if the pyramidalis muscles are in the way the fibers should be cut. The transversalis fascia is divided on a grooved director from the symphysis to the upper margin of the superficial wound. I catch the bladder with a tenaculum, on a line with the symphysis, through the prevesical fat, and with a bladder-knife I cut through into the bladder with one smooth clean incision, to prevent undue disturbance of the cellulo-adipose tissue between the bladder and the pubes and to avoid infiltration. Cutting this prevesical fat prevents it from dropping down afterward over the opening into the bladder and acting as a valve to prevent easy escape of urine, as also causing infiltration. Such a procedure also gives a smooth incision throughout, and it is almost impossible to have infiltration, even when no drainage-tube is left in the bladder, the urine being left to flow out through the fistulous tract and to be absorbed by a layer of cotton. In making the incision into the bladder little attention is to be given to any vein or veins that are sometimes met with. If cut they bleed but little. The operation is usually bloodless, so far as real hemorrhage is concerned.

The operation being completed and the patient out of bed, the annoying task follows. While suprapubic drainage is the best means that I know for treating those cases of prostatic enlargement, the fistula gives the patient a great deal of trouble. However well the fistula may drain, there will often be sufficient leakage to make the sufferer a pest to himself and to his friends. There is no possible way found as yet to keep the urine from occasionally leaking, and the fistula from occasionally inflaming. There is a constant tendency of the cutaneous orifice to contract and exfoliate that, if not carefully and properly treated, will cause a very unsightly wound and one that will be difficult to keep clean. As soon as the plug can be worn I have the patient wear it all the time—day and night. The plug I now use consists of a concavo-convex flange that coops over the mouth of the fistula and which, in some cases, aids in training the exfoliating tissues into a rudimentary penile projection that, when the patient urinates, will greatly aid in the prevention of dribbling. I show you a patient operated upon four years ago; he has no difficulty in keeping his abdomen dry, and is enabled to throw the urine several feet from his body. If he goes without the plug for a few hours his fistula so contracts that he can get the plug in again only with pain and difficulty. I had Tiemann & Co. make me a plug in two sizes of rubber, with a flat flange, which I use until the patient becomes accustomed to it. The concavo-convex flange sometimes so pinches the tissue when pressed down by the abdominal support that at first it cannot be worn. But after the cutaneous orifice has hardened for a while, the plug with the concavo-convex flange is better. The plug should be long enough to reach the bladder. But some few cases cannot tolerate the pressure of the plug in the viscus, and it should in these cases not quite reach the bladder-wall. I

have never seen two cases that could be treated exactly alike, and hence we have to be careful to adjust a plug to the comfort of each individual treated. When I first began to use the fistula-plug I had it made of silver and provided with a slight shoulder, one-fourth of an inch from the flange, to be grasped by the skin and held in position.

This shoulder, I thought, was a necessity in many cases to prevent the recti muscles from throwing the plug out. Experience has taught me that the shoulder is unnecessary and does not help matters. The best and most convenient way of keeping the plug in place is to wear an abdominal belt or support. The presence of the plug acts in preventing the artificial urethra from closing, and plays but little part in the power of retention and expulsion of the urine. There is a tendency of the entire track of the fistula to contract, but this is more pronounced at the cutaneous orifice. I do not think the recti muscles play much part in the retention of the urine, but there is formed at the vesical orifice a pseudo-sphincter that in many cases will so control the urine that the patient can retain it without dribbling for from four to six hours. I have never seen a case in whch the wash did not have to be kept up daily. So long as the fistula is a necessity, there will be sufficient pathologic causes to necessitate the daily washing of the bladder. So long as the urethra remains incompetent, from whatever cause, there will remain sufficient vesical irritation to necessitate the daily washing of the bladder. In these cases, when the fistula is created with the view of permanency, there must be an admission that the patient has an incurable malady—prostatic, urethral, ureteral, or renal. While suprapubic drainage promises much in the way of temporary relief, the fistula cannot be long tolerated without a longing desire on the part of the patient to get rid of it. With these facts before us, are we not confronted with the necessity for further surgical aid for the relief of the causes that necessitate the presence of the fistula?

To be plain, in conclusion, after we have relieved the patient by drainage sufficiently to build him up strong enough to endure any kind of surgical procedure, ought we not to remove the prostate rather than continue the fistula?

Reinfection with Syphilis.—At a recent meeting of the Royal Society of Physicians of Vienna, NEUMANN (*Wiener medizin. Presse*, 1893, No. 49, p. 1943) presented a case of reinfection with syphilis, which had been under observation in the primary attack four years previously. The case was utilized to demonstrate the curability of syphilis, and, as the treatment consisted of ten inunctions and four injections of calomel, as an argument against the protracted method of treatment.

CLINICAL MEMORANDUM.

REPORT OF TWO CASES OF AMPUTATION AT THE HIP-JOINT, IN WHICH HEMORRHAGE WAS CONTROLLED BY TRANSFIXION-PINS AND ELASTIC COMPRESSION.[1]

BY N. P. DANDRIDGE, M.D.,
OF CINCINNATI;
PROFESSOR OF THE PRACTICE OF SURGERY AND OF CLINICAL SURGERY, MIAMI MEDICAL COLLEGE; SURGEON TO CINCINNATI HOSPITAL.

THE renewed interest which has been manifested in the subject of amputation at the hip-joint, on account of new methods that have been recently introduced, leads me to think that the report of the following two cases may be of sufficient interest to engage the attention of the Society:

CASE 1. *Amputation at the hip-joint for recurrent sarcoma after previous amputation at the middle of the femur.*—H. B., twenty-two years of age, a German-American, entered the Cincinnati Hospital, June 28th. His father, one brother, and a sister had died of pulmonary tuberculosis, his mother, two brothers, and a sister being still alive. He has had a chancre and buboes, but no general manifestations of syphilis. He drinks beer freely. He has been employed on an ice-wagon, and has had to lift heavy masses of ice, resting them upon his knee. On admission there was a swelling, involving the entire circumference of the lower end of the femur, just above the condyles, with some distention of the joint. This swelling was elastic, without any marked points of softening, and was free from bruit or pulsation. Great pain was complained of. The history he gave was as follows:

Last winter he began to suffer with cramps in his left knee, and a swelling soon appeared on the outer side, with greatly increased pain. The swelling continued to grow, and involved the entire circumference of the leg. The pain became continuous and so severe that half-grain doses of morphin, given hypodermatically, were necessary to give him even temporary relief. His temperature on admission was 100°, his pulse 90. Soon after admission an exploratory incision was made over the outer aspect of the limb by Dr. Evans, then on duty in my absence, and the condition found seemed to indicate the presence of a ruptured aneurism. The incision was closed and healed promptly. On July 7th the cicatrix opened at one point, and some bleeding occurred. On the following day the man was anesthetized, and I made an incision into the tumor in the line of the recent cicatrix, after the circulation had been controlled by a rubber tourniquet at the upper part of the thigh. The knife at once entered a large cavity, from which, under strong pressure, over a pint of fluid blood escaped. An incision four or five inches long, was now made on the inner side of the leg, and for some inches the femur was found bare and roughened round four-fifths of its circumference. This condition extended down to the intercondyloid notch. At the lower part new soft bone had formed from the periosteum. No tissue resembling tumor-growth was found, and there were no layers of fibrin such as are usual in aneurism. The incision on the inner

[1] Read before the Northwestern Ohio Medical Society, Toledo, December 15, 1893.

side of the thigh enabled us to explore the main vessels, and they were found intact. From the condition here found I considered that we had to deal with a periostitis, but as the bone was so extensively affected, I judged that amputation was the wiser course; and this was performed without removing the tourniquet. An examination of the part removed left it uncertain whether the disease was an inflammatory affection or sarcomatous. A subsequent microscopic examination by Dr. Evans proved the correctness of his view, expressed at the time, of the sarcomatous character of the trouble. The wound healed promptly, and the man immediately began to gain in flesh, and in a few weeks left the house, free from pain, and some pounds heavier than when he entered.

On October 6th, just three months after the operation, the man again came into the hospital. For several weeks he had suffered pain in the stump, which had been also growing larger. The skin over the end of the stump was reddened and distended, as from an underlying growth; there was no fluctuation, and the cicatrix was perfect. Great pain was complained of.

On October 8th, the man was anesthetized, the stump laid widely open, when a condition similar to that found in the first operation was discovered. The swelling was composed principally of fluid blood; there was, however, unmistakable evidence of sarcomatous growth about the end of the bone, and amputation at the hip-joint was, therefore, determined upon. It is to the method adopted that I desire especially to call your attention, as it differs in some details from the proceeding of other operators; combining the operation of F. Jordan with elastic compression of vessels in both anterior and posterior segments of the limb by means of transfixion-skewers and elastic tubing applied as a figure-of-eight over each half. Thorough disinfection of the entire limb, groin, and buttocks had previously been carried out in anticipation of disarticulation being necessary. The knife was made to enter midway between the crest of the ilium and the top of the trochanter, and, by a slightly curved incision, was carried over the outer aspect of the latter, and then down on the outer side of the femur to the face of the stump. This incision exposed the capsule of the joint, and the knife was carried down to the bone along the entire course of the incision. One or two small vessels spouted, and were at once secured by forceps. A long steel pin, prepared for the purpose, was at once thrust through the upper part of the wound, just in front of the neck of the femur, and made to come out on the inner side above the lesser trochanter. An elastic tube was then wound in a figure-of-eight over the anterior aspect of the limb, so as to include the ends of the pin, and thus securely occlude all of the vessels in the segment. The head of the femur was then rapidly disarticulated by cutting through the capsule, and freeing the muscles attached to the great trochanter. A second pin was now passed, coming out near the first, and the posterior segment was constricted in a manner similar to the first. The soft parts, from the stump upward, were now quickly peeled off the bone, which was thus easily enucleated. Before amputating the remaining mass of muscles, a third pin was thrust through the tissues from before backward just below the first two in place. This third pin was unnecessary and useless, and somewhat in the way. A circular incision was now made through the skin, the femoral vessels isolated and secured, and the muscular mass cut through at a higher level. Absolutely no blood was lost. At points the muscles and intermuscular tissue presented a suspicious appearance, and these were carefully cut away with scissors. All visible vessels were secured and the pins then withdrawn. The loss of blood was practically none, and the operation was attended with little shock. The wound was closed throughout with the exception of a large-sized drainage-tube, which was carried into the acetabulum.

The progress of the case was satisfactory so far as the closure of the wound was concerned, but recently there have developed some symptoms that probably indicate recurrence of the trouble.

The method adopted in this case was suggested by the operation recently described by Senn, and is based on the same principle, namely, the control of hemorrhage by the independent constriction of the anterior and posterior segments of the limb above the point of amputation. Senn uses for this purpose simple pieces of tubing, without any skewer. After exposing the hip-joint by an incision similar to that of Langenbeck for excision, he disarticulates and then pushes a long pair of forceps through the tissue in front of the bone until it reaches the skin on the inner side of the thigh. The skin is incised and the forceps pushed through, and a strong piece of tubing, several feet long, is then grasped at its middle and drawn back and cut in two. The anterior segment of the limb is then constricted by tightly drawing the end of one piece across the face of the thigh, and tying or catching it by strong forceps. The posterior segment is then treated in a similar way. The entire circulation of the thigh is thus controlled by the two pieces of tubing. In a large muscular limb it would seem as though it might be difficult to secure sufficient compression of the vessels in this way, as the elasticity of a single thickness of the tubing is only available as a constricting force. The transfixion-pins, with the elastic tubing wound a number of times in a figure-of-eight over the limb must certainly secure firmer and more certain pressure, and the pins will be an additional security against slipping; and, moreover, they can be applied at a higher point, and by making the incision before the transfixion, they do not in any way interfere with the subsequent steps of the operation.

At the time of my operation I did not know that the plan I employed had been used before, but I find the account of an operation by Ogilvie Will,[1] in which the steps were identical, except that he had a single pin and applied constriction only to the anterior segment, as his flaps were cut somewhat differently. "The mode of operation I adopted," he says, "was that of F. Jordan, the skewer being passed from without inward between the bone and the soft parts in front of it through the upper end of the vertical incision, with which Mr. F. Jordan's operation commences." "The use of the skewer in hip-joint amputation originated with Spence, of Edinburgh." "The combination of Jordan's procedure with Professor Spence's skewers," he continues, "is most admirable, and really leaves nothing to be desired, for it is simple, easy, bloodless, and well adapted for drainage, while the presence of an un-

[1] British Medical Journal, November 16, 1889.

broken skin on the inner side of the thigh is a matter of no inconsiderable moment."

In Wyeth's method the closure of the vessels is secured by winding an elastic tube around the entire circumference of the limb, security against slipping being secured by two pins that pass the one within and the other without the bone. The encircling tube would seem to offer an embarrassment to disarticulation, if it did not prevent it entirely before removal. If I can judge from Wyeth's recent description of his operation, he effects disarticulation before removal of the tube, though he says it may be removed if necessary. In the *British Medical Journal*, January 4, 1890, R. J. Garden describes an amputation at the hip-joint in which he transfixed the limb from before backward, the skewer passing between the bone and the femoral vessels, the constriction of these vessels being secured by a rubber tubing carried over the skewer and the inner segment of the limb. A long inner flap was then formed by transfixion, cutting from within outward. There is no reason why this same plan could not be carried out after exposing the hip-joint by the anterior incision for excision, and subsequent introduction of the skewer after the capsule had been exposed and the joint examined. Indeed, this plan might possess great advantages in cases of tuberculous disease, when thorough examination of the joint was desirable before deciding on the necessity for amputation, or in cases of sarcomatous disease situated upon the outer and upper part of the femur. The preliminary exposure of the joint and upper part of the femur in the manner described facilitates the introduction of the skewer, which is then entirely out of the way of the manipulations necessary for disarticulation. One caution in using the skewer is necessary, namely, to see that it is strong enough not to bend under the traction of the elastic tubing.

I have recently performed a second amputation at the hip-joint by essentially the same method as that already described.

CASE II. The patient was a mulatto, twenty-two years of age, who some ten years ago had suffered an amputation at the middle of the leg for tuberculous disease of the ankle. Some months ago a new tuberculous process developed above and within the anterior superior spinous process of the ilium, which led within the pelvis. This had been several times scraped out. On November 27th his temperature rose to 102.5°, and continued high for some days, when an abscess burst on the inner side of the thigh and discharged a large quantity of tuberculous pus. No improvement followed this discharge, but the fever and septic symptoms continued. On December 6, he was anesthetized and carefully examined, full consent having been obtained for the performance of any operation deemed expedient. Close to the perineum on the inner aspect of the left thigh a large opening was found, where the abscess had spontaneously burst. The finger, introduced, passed up into the pelvis on the inner aspect of the tuberosity of the ischium, the depth of the cavity being so great that it could not be fully explored. The anterior opening, near the anterior spine, was traced downward, and bare rough bone found on the inner aspect of the ilium. A sinus from this opening passed down to the immediate vicinity of the anterior part of the neck of the femur, but no connection with the joint could be found. The joint was exposed by the usual vertical incision on the outer aspect, reaching down well below the trochanter. This incision opened a large abscess outside of the joint, which did not seem directly involved. A rapid consultation determined that the removal of the limb gave the only possible chance in the presence of such extensive disease. A single pin was at hand, and this was passed anterior to the bone and brought out on the inner side of the thigh. The only tubing available was so light that the flat rubber Esmarch tourniquet was used for the purpose of the figure-of-eight constriction, and the traction was so strong that the pin bent considerably. On this account, as an extra precaution, an Esmarch bandage was wrapped a number of times around the limb below, and a circular incision was then made through all the soft parts, down to the bone. This was left intact in order to gain the advantage of leverage in the manipulation necessary for the disarticulation. The femoral vessels were now secured in the wound, and the Esmarch bandage removed. This latter bandage I am satisfied was superfluous, and I am confident that the light tubing would alone have given perfect occlusion of the vessels. The soft parts were readily separated from the femur from below upward, and disarticulation readily affected. A number of tuberculous foci were scraped or dissected out, the various sinuses packed with iodoform-gauze, and the wound closed. After several days the temperature fell to normal and the man showed marked improvement in every way. The results so far have been entirely satisfactory.

I have long been satisfied that amputation at the hip-joint should play a more frequent rôle in the operative treatment of tuberculous disease of the hip-joint than it does.

In this case the joint-cavity itself was not involved, but there was a carious condition of the neck of the femur that might soon have reached the cavity itself, and repair in the man's condition would have been impossible.

To enumerate the steps in the operation here described, we have:

1. The capsule of the joint is exposed by an incision on the outer aspect of the limb, similar to the one used for an excision.

2. A skewer is then passed through the upper part of this incision, in front of the bone, and made to present on the inner aspect of the limb. A piece of elastic tubing is now wound in a figure-of-eight manner over the surface of the limb and ends of the pin, securely compressing all the vessels in the anterior segment of the limb.

3. The head of the femur is now disarticulated by incising the capsule and cutting through the muscles inserted into the great trochanter.

4. A second skewer is passed through the limb, coming out at a point on the inner side near the first, and constriction of the posterior segment secured in the same manner as that of the anterior segment.

5. A circular incision of the skin is now made at the point selected, the muscles are cut through at as high a level as possible, and the vessels secured.

6. The femur is enucleated and the skewers removed

7. Closure of the wound is then effected, with such drainage as the case requires.

If for any reason it is desired to secure a long anterior flap, or if for any reason it is deemed advisable to approach the joint from the front, the incision may commence "below and within the anterior spine and run down between the tensor vaginæ and glutei externally and the sartorius internally, and expose the joint," as advocated by Marsh, and the skewer can then be inserted from before backward, between the femoral vessels and the bone, in the manner described by Miles.[1] The inner segment of the limb is then constricted by elastic tubing applied in a figure-of-eight manner. Amputation may be accomplished by transfixion or by cutting the flap from without inward, or by the circular method, if desired. Such a plan might at times be more desirable than the method by the incision on the outer side.

MEDICAL PROGRESS.

Some Neuroses Associated with the Menopause.—At a recent meeting of the Medical Society of London, SAVAGE (*Brit. Med. Journal*, No. 1714, p. 995) pointed out that many mental disorders occur at the menopause that cannot be traced to this as a simple cause, though in many cases it is a predisposing cause. No special form of insanity can be called climacteric, but as a rule there is a tendency to mental depression, rather than to excitement. Any of the symptoms of the menopause may be so exaggerated as to assume serious mental aspects. For instance, there may be a kind of climacteric hypochondriasis, manifested by complaints referred to the circulation, to the head, to the skin, or to the viscera. The unnatural feelings in the skin or about the body may lead to false accusations, and the development of hair on the face may lead to miserable feelings of being unnatural or unwomanly. Deafness sometimes arises at the time of the menopause and may lead to various delusions, particularly of a suspicious nature. There is a special form of insanity which is most frequent at the climacteric period, in which, with progressive deafness, there is a progressive development of delusions of suspicion, a form that is difficult of cure and which may be parallel to general paralysis of the insane, though affecting the sensory side and not so fatal as the disease affecting the more organic side of life. There is a great tendency to the development of disorders of the reproductive organs and of the feelings associated with their function. Thus, there is frequently jealousy, irritability, and general domestic incompatibility. There is also frequently hysterical disorder of one form or another; in single women there are false ideas as to marriage proposals and the like, and in married women a re-development of sexual desire that may lead to various forms of sexual excess. There is a great tendency to seek stimulants, morphin and similar drugs. The prognosis is fairly good in many cases, though in a large proportion, especially among those that have had other attacks of insanity, recovery does not ensue. Rarely the climacteric period is attended with a relief from existing mental or nervous affections. General rather than special measures are indicated and the promiscuous use of the bromids is to be deprecated.

[1] British Medical Journal, November, 1889.

Symptoms of Syringomyelia from Syphilitic Tumors of the Spinal Cord.—At a recent meeting of the Clinical Society of London, BEEVOR (*Lancet*, No. 3664, p. 1252) reported the case of a married gardener, fifty-two years old, who two days after exposure to wet dragged the left leg. In the course of a few hours weakness appeared in the left arm, followed by wasting and numbness in the right knee. After the lapse of a week pain was complained of in the left shoulder, elbow, and wrist, with numbness in the left thumb and radial border of the forearm. In a short time weakness was observed in the left lower extremity and the numbness had extended to the groin and then to the level of the nipple. There was no affection of the sphincters, and no history of gonorrhea or syphilis could be elicited. On examination it was found that there was wasting of both upper extremities, especially of the left, with marked wasting and loss of power in the serratus magnus, supinator longus, muscles of the forearm, and intrinsic muscles of the left hand, as well as weakness of the left lower extremity; so that only the leg could be raised from the bed. Sensation was lost to pain, heat, and cold upon the whole of the right leg and the right half of the trunk up to the level of the fourth rib, while tactile perception was normal. The knee-jerk was excessive on the left side, and here ankle-clonus was present. Subsequently the loss of painful sensation extended up to the ulnar border of the right arm and to the radial border of the left forearm. There was loss of electric reaction in the intrinsic muscles of the hand. Later, paralysis of the sixth nerve of the right side appeared; the patient became gradually worse, and finally died. The case was believed to be one of syringomyelia. Potassic iodid was administered in small doses, without doing apparent good, but was not pushed, the treatment being tonic rather than anti-syphilitic. On post-mortem examination two syphilitic tumors were found on either side of the brachial enlargement of the cord, the left one passing nearer the cord than the right, but the condition of the cord precluded an accurate examination.

Fatal Intoxication with Benzene.—KELYNACK (*Medical Chronicle*, 1893, vol. xix, No. 2, p. 113) has reported the case of a woman, twenty-six years old, who, while under the influence of alcohol, swallowed about an ounce of benzene. Consciousness was lost; the pulse became quick and feeble; the respirations rapid and fairly deep; the pupils were contracted and irresponsive to light; the extremities cold, and the lips, ears, and nose distinctly blue. An intense odor of benzene emanated from the patient. The stomach was well washed out with warm water, the washings at first smelling strongly of benzene, and ether and strychnin were injected subcutaneously. In the course of three-quarters of an hour of such treatment the woman became sufficiently conscious to ask for some water. She then complained of great pain in the abdomen, and appeared also to be suffering from nausea and severe frontal headache. A little later diarrhea set in, and in spite of all stimulating treatment the pulse became progressively weaker and death took place from heart-failure twelve hours after

the ingestion of the poison. On post-mortem examination there was general congestion, and all of the organs and tissues emitted an odor not unlike that of anilin. The bronchi in several places presented small, irregular hemorrhages. The heart contained fluid and semi-fluid blood of a dark reddish-brown color. The stomach was small and contracted and contained only a little brownish fluid. At various parts of the jejunum the ridges of the valvulæ conniventes presented hemorrhages. At about the middle of the ileum there was an irregular area about nine inches long, where the mucous membrane was of a dirty-gray appearance and surrounded by hemorrhagic edges. The urine in the bladder contained albumin, cellular elements, and hyaline tube-casts.

THERAPEUTIC NOTES.

The Therapeutic Uses of Organic Extracts.—ALTHAUS (*Lancet*, No. 3666, p. 1376) has reported some exceedingly interesting observations upon the therapeutic employment of glycerin extracts of the brain and spinal cord of healthy young animals, which he designates cerebrin alpha and myelin alpha respectively. Five minims were found to be a good initial dose for hypodermatic injection, preferably into the muscles, and given on alternate days or oftener. No essential difference was observed between the action of the two extracts. The length of treatment was variable. The results were, as a rule, encouraging. The physiologic effects in healthy persons consisted chiefly of feelings of increased nervous energy and buoyancy and greater capacity for physical and intellectual exertion without much subsequent fatigue. No appreciable change in temperature, pulse, respiration, and coarse muscular force was observed, although the appetite seemed increased and the action of the bowels more free. In some cases the amount of urea excreted was increased. The principal diseases in the treatment of which the extracts were employed were the chronic degenerations of the spinal cord, various forms of hemiplegia, paralysis agitans, and epilepsy. They were also used in a case of astasia-abasia, in one of grave hysteria, for the disabilities attending old age, and during convalescence from acute diseases. The general result arrived at was that neither extract is a specific for disease of the nervous system. In cases of epilepsy, paralysis agitans, and tremor, as well as in the usual forms of hemiplegia, they were found quite useless. On the other hand, the conviction is expressed that they constitute a nervine tonic of considerable efficacy in certain maladies and conditions mainly characterized by loss of nerve-power, and particularly as an adjuvant to other remedies. In conditions habitually looked upon as purely functional it is believed that good results may be obtained from the injections without any other active treatment, while in maladies in which the organic structure of tissues is damaged they seemed to act chiefly as adjuvants and intensifiers of other treatment. Of fourteen cases of neurasthenia six were successfully treated with injections alone; six others improved under combined treatment; and in two aggravated cases there was no change for the better. Of fourteen cases of posterior spinal sclerosis the condition was improved in ten. Of four cases of spastic paralysis three greatly improved. In three cases of progressive muscular dystrophy in adults decided benefit ensued. In a few cases the treatment disagreed, constitutionally or locally. It is admitted that at the date of reporting sufficient time had not elapsed to permit an affirmation as to the permanency of the results obtained. The conclusion is expressed that the action of the extracts is twofold. In the first place they may be looked upon as a highly specialized pabulum of nervous matter by reason of the presence of protagon, cerebrin, and lecithin, as determined by chemic analysis; and in the second place they appear to act as antitoxins, as the phosphorized bodies split up under the influence of the alkalinity of the blood into glycero-phosphoric acid and cholin, which have the power of stimulating intra-cellular oxidation and the elimination of leukomaïns.

The Elimination through the Saliva of Morphin Subcutaneously Injected.—As the result of a special investigation, ROSENTHAL (*Berliner klinische Wochenschrift*, 1893, No. 49, p. 1189) has determined that when morphin is injected subcutaneously it is eliminated through the saliva in not inconsiderable quantities, even when the dose administered has been small and not in excess of minimum therapeutic amounts. Its presence is the more readily detected when the small doses have been given for several days consecutively. The period during which morphin is eliminated through the saliva cannot be determined by means of the methods heretofore in vogue of administering therapeutic doses to human beings; the relation of the quantity injected to the quantity eliminated can be only approximately determined. Morphin has a tendency to accumulate in the system, and is only gradually eliminated. A positive reaction of the gastric contents to tests for morphin and the qualitative determination do not afford conclusive and direct evidence of the presence and the amount of the alkaloid eliminated by the stomach, if the discharge of saliva into this viscus has not been excluded. In case of suspected poisoning with morphin examination of thes aliva would be indicated.

Iodo-caffein, *Iodo-thein*, *Iodo-theobromin* represent combinations of caffein, thein, and theobromin respectively, with sodium iodid. Iodo-caffein is prepared by dissolving 35 parts of sodium iodid and 65 parts of caffein in water in the cold, treating the solution with hydrogen arsenid and evaporating to dryness. There result colorless crystals, soluble in water at a temperature of 95° in the proportion of 14.5 per cent. Iodo-thein is a white powder, soluble in the proportion of 18 per cent. The preparation of iodo-theobromin is attended with more difficulty, the addition of a concentrated solution of sodium salicylate to the mixture of sodium iodid and theobromin being required. All three are unstable chemically and undergo decomposition in hot water. All stimulate the action of the heart. Iodo-theobromin increases more than iodo-caffein the energy of the systole, arterial pressure and diuresis. Neither influences the respiration or the temperature, and both are well borne. They are rapidly eliminated by the urine. The dose for adults is from 5 to 20 grains, in wafer.—RUMMO, *Sem. Méd.*, October, 1893; *Deutsche med. Wochenschr.*, No. 50.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE NOMENCLATURE OF CHEMIC TERMS.

THE extension of nomenclature in chemistry has been almost entirely in the organic department. In the inorganic field the terms are much the same as they were when their author's head rolled into the basket during the Reign of Terror. The useless "of," introduced originally through a too literal translation of French phrases, has been almost entirely eliminated, and the more satisfactory theories as to the structure of salts have brought about the substitution of such expressions as calcium carbonate and sodium nitrate for the older carbonate of lime and nitrate of soda.

In organic chemistry the resources of terminology have been highly taxed to secure a comprehensive nomenclature. In rapid succession, avenues have been opened up leading to luxuriant fields of discovery, and in many cases compounds have been obtained to which no systematic name can yet be given, and for which an arbitrary or fanciful title must, for the time being, suffice. Organic compounds being in great part composed of the same elements, no system based merely on indicating these elements can be applied. This simple method is practicable in the mineral chemistry. In the nomenclature of organic bodies the aim is to indicate structure and structural relationships; names based on any other system are temporary or accidental. Marked advance was made in April, 1892, by an international convention which met at Geneva to revise the nomenclature of chemic terms. It is regrettable that the new Pharmacopeia did not observe the salient points of the decisions of this convention, for there is little doubt that long before the next revision is made chemists and pharmacists will have accepted the system. This nomenclature is, of course, distinct from the question of reformed spelling, although the committee of revision appears not only to have confused the two issues somewhat, but also to be inconsistent with itself. Thus, in the preface, the committee states that it was considered inadvisable to drop the final "e" in "chloride," "bromide," etc., yet in the body of the work the "e" is dropped in "acetanilid," which is as much an innovation in spelling as "iodid." The terms "glycerol and benzene" are referred to as if they were novel or unusual, whereas they are in extended use in both America and England, and no chemist who is careful as to his phraseology now uses benzol as the name for the benzene. In fact, benzol is now a name, in the coal-tar trade, for a product containing several ingredients. It is also a matter of regret that the absurd spelling "naphtalin" is used for "naphthalene;" nor is it clear why a recent reform in German spelling has been allowed sufficient influence to make "naphtol" out of "naphthol." The disadvantage of the termination "ine," which the committee thinks useful as indicating basic properties, is shown in the case of caffein, the title of which to the final "e," which the Pharmacopeia gives it, is doubtful. A further eccentricity in nomenclature is shown in the rule of forming the Latin names of the salts with a genitive construction, while the English equivalent is put in the nominative. Thus, *potassii chloras* is the equivalent of potassium chlorate. The retention of the term hydrate, when almost all chemists have adopted the term hydroxid, which is so much more in accordance with our modern notions of structure, is also unfortunate.

The United States Pharmacopeia is not a textbook of chemistry; it is not even addressed to the teachers and workers in chemistry outside of medicine, nor has it any authority with them. In its chemic terms, therefore, it should defer to, not resist, the tendency of pure chemistry. The nomenclature which has received the approval of the American Association for the Advancement of Science, of the Association of Official Agricultural

Chemists, of the American Chemical Society, of the Chemical Society of England, and of such journals as the *Chemical News*, should not be dismissed as awaiting acceptance. As the committee adopts without hesitation the rules for botanic nomenclature promulgated by the Botanical Club of the American Association for the Advancement of Science, why should not the Chemical Section of the same Association be given equal weight?

A judicious approval of the generally accepted points of nomenclature in chemistry would have done much toward securing the adoption of the exact phraseology by physicians, who stand sorely in need of correction in this respect.

The following summary includes the more important points in the nomenclature of organic chemistry as now generally accepted:

–ol indicates alcoholic structure, *i. e.*, presence of the group HO (hydroxyl), *e. g.*, alcohol, glycerol, phenol.

–ose indicates a carbohydrate, *e. g.*, glucose, although it is also occasionally applied to the results of digestion of proteids, *e. g.*, albumose.

–ase indicates an enzym, or non-organized ferment, *e. g.*, diastase. This termination is at present restricted generally to enzyms of vegetable origin, but it should also be used with animal enzyms—which, however, usually end in "in." It would thus be better to say *pepsase* and *trypsase*, rather than *pepsin* and *trypsin*.

–ane indicates a saturated hydrocarbon.

–yl, *–ene*, *–enyl*, and *–ine*, indicate hydrocarbons.

According to the American system of orthography the only case in which "*ine*" is used, is as a termination for certain hydrocarbons. The preceding vowel is long.

–al indicates aldehydic structure.

–in is of no precise significance, and is mostly applied to bodies the structure of which is not yet known.

–id is similar to "in."

As to prefixes:

Ket– indicates the molecule CO in certain structural relations.

Azo–, *diazo–*, and *hydrazo–* indicate compounds in which nitrogen atoms are linked in various ways.

Nitro– indicates the group NO_2.

Am– indicates the group NH_2.

Im– indicates the group NH.

Thio– indicates sulfur, especially replacing oxygen.

The word *sulfonic* indicates the group HSO_3.

Except as noted, the termination *–ine* is not now used by American chemists. English writers, however, use it to signify basic properties, regarding *–in* as the proper term for non-basic bodies. They thus distinguish between salicin, which forms no salts with acid, and morphin, which does. It must be noted, however, that such methods are not in accordance with the tendency of nomenclature which seeks to express structure, not properties. The organic bases or alkaloids are not all of the same type, and when their structure is elucidated systematic names will be found for them. Until then there is no particular gain in indicating them as a group.

THE PHYSICIAN AS A SOCIOLOGIC FACTOR.

WE hold that it is directly within the physician's sphere of action to interest himself in all such movements as tend to prevent disease and improve the health of the community in general. Whilst it is undoubtedly the principal function of the physician to cure particular cases of disease, a large conception of his duty makes it plain that he should also act as a preventer of diseases in general. Such, indeed, is the tradition of the profession.

We are aware of the fact that the "city doctor" who has attained to any degree of eminence is usually a very busy man. With the ordinary duties pertaining to his private practice he combines those of teacher, author, investigator, and hospital official, to say nothing of what is demanded of him by the various scientific bodies which are honored by his fellowship. It would be extremely inconsiderate to ask such a one to devote any considerable portion of his time to the interests of the community or to the public in general. As a scientific investigator he may discover truths of the greatest importance to the whole world, and hence one may become a public benefactor who has never been seen or heard outside of his laboratory.

There are, however, many young members of the profession who, unfortunately for themselves, are not in possession of a lucrative practice, who are not particularly trained or expert in scientific research, and whose experience is yet too limited to permit them to become authors or teachers. They are, indeed, practically wasting much valuable time and ability. These "patient-waiters" if we so dare to term them, are found in the country towns, as well

as in the city, and we believe they can be of immense service to any community and likewise benefit the science of medicine and themselves by taking a more active part in those social questions of the day that have relation to preventive medicine.

It has been said that "No other profession is doing so much toward ending its own existence as the profession of medicine." This is true, even if we consider ourselves merely as therapeutists, or curers; but it is especially true of every effort in the line of prevention of disease, because that must limit the scope of our action as to its treatment. But if, as healers of disease, we are making ourselves less necessary with each new discovery, can we not make ourselves more useful as custodians and preservers of health.

For example: We all know how clearly preventable is that host of diseases arising from want of cleanliness. There is a dangerous ignorance on this subject among the people generally. Cannot the young physician do something to educate the masses in the matter of hygiene? It is not wise to overcome ignorance by force or expect a faithful adherence to sanitary principles if the necessity for such laws is not understood by the people themselves or by those who administer the laws.

Movements that relate to the better housing of the poor, to prevent overcrowding, that seek to establish breathing-spaces in the crowded parts of cities; efforts to secure better streets, pure water, less noise, less imperfect drainage and better disposal of garbage—all these are truly health-questions, and deserve the active coöperation of the young physicians, and the older ones too, for that matter.

The reform of municipal government is not entirely foreign to medicine, as without good government sanitary measures are not likely to be properly executed, and, therefore, both as a citizen and as a physician every member of our profession ought to be interested in municipal reform, and the younger members especially should do their part in its advocacy. Crime, pauperism and inebriety are called social diseases, yet they are closely dependent for their causation on physical disease, and on the other hand many physical diseases owe their existence to these social evils. Some go so far as to call all crime and inebriety disease, physical disease; others consider them the outcome of social conditions. It is the old question of inheritance, predisposition, and contagion, so often discussed in medical literature, carried into the morals of the world. Whatever the answer may be, the dependent and delinquent classes are more and more, in one way or another, coming under the care of medical men; they are being looked upon as abnormal and pathologic, rather than immoral and depraved.

All studies, therefore, of the causes of social diseases are not without the domain of medicine; and a knowledge of the social conditions of the masses, gained from actual observation, must be of value in such studies. In the smaller towns education of the old and young in health-matters, school-hygiene, etc., is as necessary as in the larger cities. Epidemics of contagious disease often create great havoc in the village communities from lack of centralized power to prevent the spread or discover the cause.

Many towns have already organized boards of health consisting of medical men. Every community, no matter how small, should have such a department, and it is for the younger men to form and control such an organization, and to guard it jealously from political debauchery. We know that no such encouragement is extended to the young physician who wishes to carry the "gospel of health" to the heathen in the city slums as he receives who, as medical missionary, declares his intention of seeking to convert the far-away African or Hindoo. But as a profession we are self-sacrificing enough to do our duty whether we see a return for it or not.

We believe that the physician can play a more important part than heretofore in public affairs; that it is not beneath his dignity nor without his province to do so; that the younger members of the profession can make themselves especially useful as educators, and that the science of medicine itself can be benefited in consequence.

EDITORIAL COMMENTS.

Authority of Boards of Health to Suppress Nuisances.—In a matter so serious as that of the public health, the Court of Appeals holds, in the recently decided case of Board of Health *v.* Copcutt, that a board of health ought not to wait until some citizen is sick or dead before it prevents or abates the nuisance causing the injurious result. Thus, when a statute is provided specially for the removal of a nuisance, the people are not compelled to await its completion, but are awarded an injunction to restrain the further erection, and compel the removal so far as erected. So a board of health has power to prevent a reconstruction and a reinstatement of what it has declared to be, and what the court has found in fact was, a public nuisance. In this particular case,

which was an action brought by a board of health to enjoin the maintenance of a dam, the owner contended that when he built the dam the stream was clean, and the water pure; that he never did anything to pollute it, or to make it injurious to health; that it came into that condition from the acts of others; and that his property was destroyed, and he was forbidden to restore it, without any fault of his own. The court answered to this that the dam and pond were his. He had a right, it was his duty, to keep them clean and safe, or dispense with them entirely if he could not. His dam was a pocket to catch and hold all filth thrown in above. He well knew it, and could not sit still and suffer his own property to become an intolerable nuisance, and say it was not his fault. When pestilence is forcing its way into our harbors, and danger and death approach through all rot and filth, it is the condition with which boards of health must grapple, and the condition which must be abated or removed, without regard to the question who caused the trouble. However innocent the owner of the property may be in creating the condition or maintaining it, he is bound to abate it upon the proper official request, and, if he refuses, he becomes at once responsible for the existing condition, as continuing a nuisance which it was his right and duty to remove and suppress.

The Editor Blesses the Advertisers.—We feel sure that one of our active Western contemporaries (who, by the way, has been making a most commendable fight for medical-practice reform in his State) would feel sorely aggrieved if any but himself had suggested the possibility implied in the following quotation taken from a recent number of his not uninfluential journal: "Not infrequently as much or more valuable information may be found in the advertising than in the pages devoted to what is known as pure reading matter." Unconsciously, perhaps, with the thought of removing the force of this imputation he endeavors to restore a condition of equality by introducing into his editorial columns commendatory notices of a number of his (pecuniarily) most important advertising patrons. To augment this missionary work we would suggest that our ingenuous contemporary might make up his entire journal with advertising matter. There would then be no odious comparisons or invidious distinctions to make, and he might feel sure that the profession were being well educated, according to the standard that he seems to have established.

Original Articles in The Medical News.—The *Journal of the American Medical Association* publishes the results of a statistical inquiry as to the original articles that have appeared in the principal weekly medical journals of the United States during the past year. We are gratified to learn that THE MEDICAL NEWS in the last volume devoted a larger number of pages to original articles than any of its competitors, the *Journal* of the Association of course excepted. We doubt not if the distinguished editor of the *Journal* had been permitted to have his way—that is, if he had been allowed to use his excellent editorial discrimination—the number of his pages of original articles would have been much less. We reproduce the figures in by no means a boastful spirit, but we confess our pleasure in finding that other periodicals with a higher subscription price, and claiming a greater number of total pages, do not in the year give as many pages of orginal articles as THE NEWS. This just pride is increased when we recall the fact that every contributor to the columns of THE NEWS has received due compensation, a feature which we believe to be peculiar to THE NEWS. "The laborer is worthy of his hire." We append the *Journal's* figures.

July 1 to December 30, 1893.	Journal American Medical Association.	New York Medical Record.	New York Medical Journal.	Boston Medical Journal.	MEDICAL NEWS.
Number of original articles . .	240	176	158	132	175
Number pages original articles	665	334	380	300	397
Total number pages	1024	860	816	660	756

The Exciting Cause of an Injury Viewed Legally.—According to a decision of the Supreme Court of Wisconsin, in the case of Vosburg *vs.* Putney, medical experts can testify to the exciting cause of an injury. In this case action was brought to recover for an injury caused by one boy kicking another, a little below his knee, while in school. The defence made was that if disease existed in the boy's leg before the injury complained of was inflicted, and such injury merely served to accelerate its progress or to locate the point of suppuration, and was not the original cause thereof, or if the proximate cause of the inflammation in the leg was the presence of pus-germs which obtained entrance by way of a previous wound above the knee, no recovery could be had. But the court refused to so instruct the jury. The law on this point was held to be that if the kick inflicted was the exciting cause of the injury complained of, and such injury was the natural consequence of the kick, the one inflicting it was liable therefor, although the physical condition of the person kicked might have aggravated the injury. The jury in this case assessed the damages at $1200.

The Use of Patent Medicines as Evidence of Legal Want of Care.—A so-called patent medicine may or may not be a curative agent, and there must be some evidence upon this point before an issue of fact is raised. So holds the Court of Civil Appeals of Texas, in the recently decided case of Gulf C. & S. F. Railway Co. *vs.* Brown, which was an action brought by the latter to recover damages from the railway company for a personal injury, and in which one of the defences pleaded, besides a general denial, was that the man had not secured proper treatment, or taken proper care of himself, thereby aggravating his injuries, and also having resorted to the use of patent medicines. The fact that he had used, and applied to his hurts, a patent medicine, the court continued, was not evidence of the want of care in treating his injuries. It seems strange that a railroad or any other product of civilization could have penetrated so far as the dense barbarism of that judge's district.

Comparison of City Death-rates.—Our esteemed contemporary the *Philadelphia Press* takes exception to the views advanced recently by THE NEWS concerning the percentage of deaths in some large cities. The *Press* argues that the higher death-rate of New York over London may be accounted for to a considerable extent by the greater extremes of temperature, and by the overcrowding in the tenement districts. Extremes of temperature are certainly as great in Chicago as in Philadelphia, and comparison of the numbers of deaths from diseases of the respiratory tract does not bear out the contention of our excellent contemporary. It must also be noted that it is not likely that New York is more overcrowded than some districts of London and Berlin, and further analysis of the mortality statistics shows that the tenement district in New York is not distinguished by a specially high death-rate. Infant mortality, as the *Press* notes, is high in American cities during the midsummer, but a large proportion of such deaths are due to preventable diseases. When we turn to the typhoid statistics we see the difference in the sanitary state very clearly. London has a typhoid death-rate of 0.49 per thousand per year, Berlin slightly less, 0.42; while New York's death-rate from this disease is more than double that of Berlin, that of Philadelphia over five times, and that of Chicago still more.

If the population of Philadelphia equalled that of London, with no alteration of its sanitary conditions at present existing, there would be in Philadelphia twenty-seven hundred deaths annually from typhoid fever against four hundred and twenty-five in London. The *Press* also argues that the somewhat lower death-rate (from all diseases) in Chicago than in New York or Philadelphia is due to the greater number of young adults in the Western city. But would not the same argument apply to our Eastern cities in comparison with London and Berlin? The proportion of young adults must be rather larger in American than in European cities. If this is the case the death-rate is still more disproportionate than the figures at first sight indicate. It is undoubtedly true that natural and irremediable conditions operate in some cities to render the mortality higher; but it is also true that an analytic study of the mortality lists shows that a large element of fatality is contributed by diseases the causes and means of prevention of which are known and practicable to municipal administrations.

It strikes us that it would be more needed advice to our citizens to warn them of such things as the dangers of drinking the sewage of several hundred thousand people rather than to blunt the edge of needed criticism by labored arguments in the old art of *laisser-faire*.

Enterprise, Journalistic and Professional, is displayed by the custom quite common nowadays in certain parts of the country, for the local daily newspaper to publish a special edition largely devoted to biographic and eulogistic notices of "Successful Doctors." The details of the successful careers are blazoned with liberal colors, the office hours, specialties, telephone-numbers, etc., following in each case. The fellow who pays the most, and furnishes the most glowing and particularized accounts of himself, and who orders the greatest number of hundreds of extra and marked copies for distribution to his *clientèle*, is, of course, he that "takes the cake." It is mortifying to find certain names in these lists of dishonor.

Non-expert Testimony as to Blood-stains.—Persons not experts are allowed, in proper cases, to testify as to what they have seen, when, perhaps, expert testimony would be more conclusive. Thus the Supreme Court of Missouri holds, in the recently decided case of State *v.* Robinson, that a non-expert can testify that the stains which he observed on a certain garment "looked like" blood-stains. This court also says, in the same connection, that frequently the *opinion* of a witness as to the appearance of an object he has seen is the best and only evidence obtainable; nevertheless it is competent.

The Physicians of Ohio have been holding a convention at Columbus, and have formulated a medical-practice bill for presentation to the Legislature. It is thought that at last some sort of control of the medical abuses of the iniquitous conditions prevailing may at last be reached. Any five men, simply upon application to the Secretary of State, can secure a charter for a college and grant diplomas for any or for no consideration whatsoever.

The Way to Stop the Reading-notice Evil.—An eminent professor in one of our universities writes us that, after vainly protesting to the editor of one of our foremost medical journals against concealed advertisements in the reading columns, he has ordered the journal to be sent to him no longer.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, held at the New York Academy of Medicine, Tuesday Evening, January 2, 1894.

DR. M. ALLEN STARR, PRESIDENT, IN THE CHAIR.

DR. J. LEONARD CORNING narrated the case of a young man, eighteen years old, who had received a severe kick directly over the right ear while engaged in a game of foot-ball. He was first seen by Dr. David Webster, who, upon careful examination, found that there was total deafness on the right side; aërial conduction and bone-conduction were suspended. There was no trouble in the middle ear, and the drum was in perfect condition. There was slight bleeding from the external ear, but no evidence of fracture. A rapidly interrupted faradic current was applied to the ear and allowed to pass for about ten minutes, when the hearing was so far restored that the patient could hear a watch at a distance of six inches. Before making the application, the external meatus was plugged with absorbent cotton moistened in salt-solution. A severe tinnitus that had coexisted with the deafness was also relieved. Dr. Corning said that he had no idea what the lesion was, or why improvement followed the use of the current; it was employed simply as an empiric measure. The young man's hearing is now entirely restored. There was no suspicion of hysteria. The visual field was not tested.

DR. DAVID WEBSTER said that he supposed the deafness was due to concussion either of the auditory nerve or of the labyrinth, of which he has seen cases reported.

Temporary blindness has been produced by a sudden blow on the brow, without ophthalmoscopic or other lesion. Most of those cases, however, are due to fracture of the base of the skull, involving the optic foramen and producing nerve-atrophy. He has never seen a case similar to the one reported.

Dr. Starr suggested that the case might have been one of traumatic hysteria or concussion of the auditory nerve. In consultation with Dr. Jacobi he recently saw a case of total deafness of central origin, in which temporary improvement in the hearing was produced by the use of a strong galvanic current—about six milliampères, which is a strong current for the acoustic nerve.

Dr. J. Arthur Booth said that in a number of cases of tinnitus he has employed the galvanic current with marked benefit. He also never saw a case similar to the one reported.

Dr. Ralph L. Parsons read a paper entitled "Report of a Case of Akromegaly." The patient was a man, thirty-six years old, with a negative family history. He had never had venereal disease and had not used alcoholic stimulants. He was in good health until eighteen years ago, when he had an attack of malarial fever. From this he recovered and has had no recurrence since. Ten years ago he was told that he stooped and carried his head to one side. Two years later he began to suffer with pain in the back of the head. This came on mostly at night, and not oftener than once a week. Subsequently the headaches occurred more frequently by day than by night. Latterly they have increased in frequency and duration and have often been excruciating in degree. The pain was usually most severe at the occiput, but would also involve the left parietal and frontal regions; the right side of the head was unaffected. About six years ago his attention was first called to the large size of his hands. He then for the first time perceived that they were of extraordinary size. He does not know for how long a time this increase in size has been taking place. He cannot say whether or not the hands have increased in size during the past six years.

In October last the patient weighed 227 pounds. He presented no pronounced symptoms of organic disease. His hair was rather coarse, but natural in condition. The left ear was slightly thickened. The forehead was retreating; the superciliary ridges quite prominent. There was no exophthalmos. The malar bones were rather prominent; the cheeks appeared sunken; the nose was broad and full at the nostrils; the lips were normal. The tongue was decidedly enlarged, obstructing free articulation; the alveolar processes normal; the teeth not separated; the chin was elongated. The head was inclined strongly and habitually to the left side and forward. The hands were large and spade-like, the right hand being decidedly the larger. The soft tissues of the hands and fingers were firm and resilient, as though infiltrated by an elastic substance; they did not pit on pressure. The wrists were rather large; the arms normal; the thorax and pelvis normal. The feet were large, but perhaps not more so than in the case of many men of the same weight. The patient has perspired very freely for the past ten years; but of late the perspiration has been decidedly offensive. Besides the headache referred to, the patient also complained of pain in the left ear and eye, the latter coming on after reading or using the eye in a strong light. He does not think that his eyesight has become impaired. Appetite and thirst are excessive. There are no marked mental symptoms.

On the 21st of October, by advice of Dr. Starr, the patient began the use of a thyroid extract, five drops three times daily. The dose was gradually increased until the man received fifteen drops three times daily. With the exception of tonic baths, general hygienic measures, and a regulation of the diet, no other treatment was given. At the present time the patient reports that he is feeling decidedly better. He is more cheerful, and his headache has been relieved to a great extent. It has not, however, entirely disappeared. There seems to be no change in the dimensions of the hands. The weight has increased rather than diminished. There has been a great improvement in the subjective condition, but there is still a reasonable doubt whether this improvement is due to the direct action of the medicine or to the patient's mental status induced by the fact that something is being done for his relief.

Dr. Starr said that the use of thyroid extract in the case narrated is purely empiric. The supposed lesion of akromegaly is an increase in the size of the pituitary body. It is questionable whether it is in any way related to the thyroid gland. The eye-symptoms in the case narrated are interesting, because in two other cases of akromegaly coming under observation there was a concentric diminution of the visual field, and in one hemianopsia; the latter symptom is quite common, and is probably due to pressure on the chiasm by the enlarged pituitary body. In one case of akromegaly seen at St. Luke's Hospital death resulted from pneumonia, and at the autopsy the pituitary body was found to be normal. There was nothing to account for the peculiar growth of the bones.

Dr. Parsons said that it is generally supposed that there is a sort of relationship between akromegaly and myxedema; whether this belief is well founded or what that relationship is is not known.

Dr. J. Leonard Corning read a paper entitled "Some Less-Cultivated Phases of Psychology; Considerations on the Genesis of the Feelings, or the Relation of Desire to the Will-function; Practical Deductions therefrom concerning the Management of Various Psychopathic Conditions." He traced the relationship of the desires to the function of the will, and showed the importance of psychic influences in the correction of certain morbid mental conditions. In neurasthenia, simple melancholia, hysteria, and other functional nervous troubles the desires are best evoked and fostered through the special senses, notably through the sight and hearing, while at the same time the receptivity of the sensorium is increased by proper stimulation. The effect thus gained is not necessarily evanescent. Due heed should also be given to the general bodily condition. Nutrition must be improved and gouty and other morbid tendencies antagonized. The question of influencing the mind to the advantage of the patient is certainly an important problem in neurology, and one well worthy of discussion. In concluding the paper reference was made to the loss of prestige that has apparently overtaken hypnotism, which in too many instances only

served to substitute a veritable neurosis for the morbid condition that it was sought to modify.

DR. W. H. THOMSON said that his own plan in the treatment of melancholia has been not to appeal to the will of the patients at all; it is only discouraging to them to tell them to think less of their condition; their train of thought should be involuntarily changed by new objects brought to their senses, either through the eye or the ear. By means of a change, using the word in its broadest sense, a change of scene, of surroundings, and of society, the endeavor should be made to produce an involuntary displacement of the morbid ideas.

DR. WILLIAM H. THOMSON read a paper entitled "Ergot in the Treatment of Periodic Neuralgias. He gave the histories of a number of cases of severe periodic neuralgias in which the symptoms were promptly relieved by the use of ergot in large doses. In all of these cases the disease was of long standing, and the usual remedies had been employed without avail. The method of administering ergot in migraine is as follows: The fluid extract of the drug is employed, combined with an equal quantity of elixir of cinchona, to overcome the tendency to cause nausea. Two drams of this mixture are to be taken in water as soon as the premonitory symptoms of the headache are noticed, and the patient is advised to lie down and keep very quiet. If, after an hour, the headache continues, a second similar dose is taken, and then a third in another hour, if necessary. As nausea is such a general accompaniment of migraine, it is provided that if either of the doses be vomited, the medicine should then be taken in an enema of two ounces of water. This medication, it was said, rarely fails to arrest the attacks, even in cases of long standing, and with a preventive course of intestinal antisepsis in the intervals, the relief from the malady has often proved permanent.

DR. JOSEPH COLLINS said that he had recently employed ergot in the treatment of several cases of periodic neuralgia. In one case, in which huge doses of Warburg's tincture, quinin, potassium bromid and iodid had been given without benefit, dram-doses of ergot were followed by a marvellous improvement. In another case, in a lady, forty years old, who had long been under treatment for migraine, the therapeutic value of ergot was discovered accidentally; it was given to check a menorrhagia and it at the same time relieved the headache.

DR. C. A. HERTER said that in the treatment of cases of migraine he lays greater stress upon the diet and nutrition than he does upon drugs. He employs very few drugs, chiefly aconitin. He is decidedly opposed to the use of the antipyretics.

DR. CORNING said it is important to determine whether the pain is extra-cranial or intra-cranial. He referred to the value of compressed air in relieving intra-cranial pain. External pains, on the other hand, are aggravated by the compressed-air treatment.

DR. THOMSON referred to the fact that quinin, even in small doses, when combined with ergot, appears to produce cinchonism much more quickly than when given alone. In only one of the cases reported was there any antecedent history of malarial infection, and in that case the patient simply had resided in a malarious district. Very likely there was a malarious element in the other cases, of which the nervous symptoms were the only manifestations. Dr. Thomson also referred to the fact that intercostal neuralgia is often accompanied by sciatica; also the occurrence of sciatica after pleurisy. The latter combination he has noticed in about twenty cases.

NEWS ITEMS.

The Medical Society of the State of New York will hold its eighty-eighth annual meeting February 6th, 7th, and 8th, in the City Hall, at Albany. The following provisional scientific program has been arranged:

Hemorrhagic Serous Effusion into the Pleura, with Report of a Unique Case; by William S. Cheesman, Auburn. Researches on the Eliminating Power of Diseases, and the Relation between Vaccina and Enteric Fever; by William Finder, Troy. Pneumonia of the Aged; by John H. Pryor, Buffalo. Diagnosis and Nomenclature of Fevers—second paper; by Nelson G. Richmond, Fredonia. The Therapeutics of Oxygen; by Arnold W. Catlin, Brooklyn. Simple Methods in the Diagnosis of Nervous Diseases; by E. C. Spitzka, New York.

Discussion on Diphtheria.—Pathology—Status Præsens; by Thomas E. Satterthwaite, New York. Observations on Diagnosis, and some Sanitary Aspects; by A. Walter Suiter, Herkimer. Croup and Diphtheria—Unity or Duality; by William H. Daly, Pittsburg, Pa. The Comparative Status of Intubation of the Larynx; by Joseph O'Dwyer, New York. Complicated Intubation of the Larynx; by William Hailes, Albany. The Local Treatment; by Abraham Jacobi, New York. The General Treatment; by Edward F. Brush, Mount Vernon. The Use of Tartar Emetic in Diphtheria; by H. DeV. Pratt, Elmira.

Treatment of Depressions in the Skull of the Newborn; by David D. Jennings, New York. Immediate Trachelorrhaphy; by Henry C. Coe, New York. Lymphadenoma of the Uterus; by H. J. Boldt, New York. Senile Endometritis; by A. J. C. Skene, New York. Treatment of Endometritis; by Herman E. Hayd, Buffalo. Nine Years' Experience with Alexander's Operation for Shortening the Round Ligaments of the Uterus; by Paul F. Mundé, New York. Pelvic Abscess; by Walter B. Chase, Brooklyn. A Case of Hysterectomy for Retention of the Menses; by William Gardner, Montreal.

Discussion on Menstruation and its Abnormalities.—Introduction and Normal Function; by Andrew F. Currier, New York. Dysmenorrhea—its Causes and its Treatment; by Howard A. Kelly, Baltimore, Md. Profuse Menstruation; by Charles P. Noble, Philadelphia, Pa. Scanty Menstruation; by Franklin Townsend, Jr., Albany. Irregular Menstruation; by Charles A. L. Reed, Cincinnati, O., and E. W. Cushing, Boston, Mass. Menopause—Natural and Artificial; by Arthur W. Johnstone, Cincinnati, O.

Urethral Caruncles; by Edward N. Liell, New York. The Physical Causes of Sexual Debility in the Male, as Distinguished from the Psychical Causes; by F. R. Sturgis, New York. The Surgical Treatment of the Prostate Gland; by Seneca D. Powell, New York. The Fable of the Egg; by William S. Ely, Rochester. Artificial Immunity; by Henry R. Hopkins, Buffalo.

Clinical Notes on Psoriasis, with Especial Reference to its Prognosis and Treatment; by L. Duncan Bulkley, New York. Spinal Supports and Braces—the Indications for their Use—History and Modern Perfection (to be illustrated with forty lantern-slides); by A. M. Phelps, New York. Histology and Pathology of the Spinal Cord (illustrated with lantern-slides); by Wm. C. Krauss, Buffalo.

Discussion on Abdominal Surgery.—Disputed Points in the Treatment of Pelvic Surgery; by Joseph Price, Philadelphia, Pa. Influences Affecting the Results of Abdominal Operations; by J. F. W. Ross, Toronto, Canada. Hemorrhage after Abdominal Section: its Place in Statistics; by A. H. Buckmaster, New York. Cysts of the Epigastrium; by Dudley P. Allen, Cleveland, O. The Technique of the Abdominal Incision; Methods of its Closure and its Subsequent Management; by W. W. Potter, Buffalo. Operative Procedure for the Relief of Obstruction of the Common Duct; by W. E. B. Davis, Birmingham, Ala. Two Cholecystotomies for Gall-stones with Recovery, with Remarks on Operative Methods based upon Five Cases; by William Wotkyns Seymour, Troy. Gall-stones, the Exciting Cause of Malignant Disease; by Rufus B. Hall, Cincinnati, O. Appendicitis; by Charles McBurney, New York. An Analysis of 150 Personally Observed Cases of Appendicitis; by George Ryerson Fowler, Brooklyn. A Conservative View of the Treatment of Appendicitis; by William S. Tremain, Buffalo. Some Observations Relative to the Treatment of Suppurative Appendicitis, with Report of Cases; by Willis G. Macdonald, Albany. Palpation of the Vermiform Appendix; by G. M. Edebohls, New York. The Inch and a Half Incision, and Week and a Half Confinement in Appendicitis; by Robert T. Morris, New York. Report of a Case of Post-peritoneal Abscess from Duodenal Ulcer, with Presentation of Specimen; by L. S. Pilcher, Brooklyn. Intestinal Perforation in Strangulated Hernia; by William B. Dr. S. Guttmann, editor of the *Deutsche medicinische Wochenschrift*, died on December 21st at Berlin as the result of a virulent attack of influenza, at the age of fifty-four years. The post-mortem examination disclosed the existence of an adherent pericardium, and sclerosis of the aorta and coronary arteries. In addition to his editorial labors Guttmann was an able clinician and contributed generously to medical literature. He was collaborator with Leyden of the collective investigation into the influenza-epidemic of 1889–90, made at the instance of the Berlin Society for Internal Medicine.

Dr. Richard C. Norris has been elected physician in-charge of the Preston Retreat, in succession to Dr. Joseph Price, who had resigned. Dr. Norris was graduated from the Medical Department of the University of Pennsylvania in 1887, and was at once elected a resident physician in the Philadelphia Hospital. He has for a number of years been an instructor in Obstetrics in the University of Pennsylvania, and is also one of the editors of the *Annals of Gynecology and Pediatry*.

International Sanitary Congress.—The President of the United States has appointed Dr. E. O. Shakespeare, of Philadelphia, Dr. Stephen Smith, of New York, and Dr. P. H. Bailhache, of the United States Marine-Hospital Service, delegates to represent the United States at the International Sanitary Congress, to be held in Paris on January 24th.

A Four-years' Course at Jefferson Medical College.—At a meeting of the Faculty of Jefferson Medical College, held on January 8, 1894, it was unanimously resolved to institute a compulsory four-years' course with the session of 1895–96.

The Lehigh Valley Medical Association will hold its Sixth Winter Conversational Meeting at the Eagle Hotel, Bethlehem, Pa., on Thursday, January 25, 1894, at 10 o'clock A.M.

CLINICAL REMARKS ON THE EXTERNAL USE OF GUAIACOL IN REOUCING HIGH TEMPERATURE IN TYPHOID FEVER AND OTHER FEBRILE DISEASES.[1]

BY J. M. DA COSTA, M.D., LL.D.

THE first case to which I shall call your attention this morning is one of continued fever, of low type. It is not, however, on account of the febrile symptoms, it is not on account of the diagnostic points of the case, that I now bring this patient into your presence, but rather because we have been pursuing a line of treatment which, in many respects, is untried, and which, I think, gives promise for the future.

This boy, who is sixteen years of age, a peddler, was admitted to the hospital on the 7th of this month. He stated that he had been feeling ill for some time, and that for about two weeks previously he had experienced headache, weakness, loss of appetite, and general bad feelings, for which he had consulted a physician four days prior to admission, but that he did not go to bed until he came into the ward. When admitted he had a temperature of 105.4°. His other symptoms were not of a grave character; in fact, the high temperature was the most striking feature. There was no headache, no delirium, and he had fairly good rest at night; I am sure I am right in saying that it was a case of extremely high temperature in which the nervous symptoms did not correspond with the degree of temperature. As regards the pulse, it ranged from 94 to 104; as regards the respiration, it was observed to be from 28 to 32 in a minute; the bowels were constipated. There were signs of slight pulmonary congestion in the lower lobes. No eruption was present, although it was diligently sought for; there is certainly none to-day upon his chest and abdomen, as I examine him before you, nor has any been found on the back. He has now reached the eighteenth day of the disease, as nearly as we can make out. His temperature this morning is 101.8°. He has no cough; the splenic dulness extends to the margin of the ribs. The absence of diarrhea is still to be noted. In truth, the abdominal symptoms, so usually present in typhoid fever, were so markedly wanting that, for a time, we doubted whether, after all, this was not really a case of influenza of low type in which the temperature, by way of exception, had attained extraordinary height. But the long duration of the disease, now in its eighteenth day, and the steadiness of the fever, point to the conclusion that it is a case of typhoid fever from which the usual intestinal symptoms are absent.

Yet it is not in order to discuss the subject of diagnosis, however interesting, that I bring this case before you, but rather to examine the means that we adopted to check the fever and to reduce the height of the temperature. Now the usual means for the relief of the high temperature in typhoid and other continued fevers is the cold bath; it is for the most part safer and better than the internal administration of the antipyretics of the coal-tar series. The present case is one in which you may say that the cold bath was preëminently indicated; and so it was. But in this patient I decided to resort to an article that we had been using with good results in other cases in the hospital for reducing temperature. I might state that I had long been looking for a therapeutic agent which, externally employed, would reduce temperature in cases of fever, without the disturbance incident to the bath. Some years ago I made use of spongings with menthol added to water. The patients liked this treatment extremely, but we gave it up; for, notwithstanding the attention of our nurses, and the faithfulness with which the sponging was kept up, we did not succeed in keeping down the temperature, when it ran very high, more than a degree below what sponging with cold water alone did.

I do not, save in rare instances, approve of the use of the ordinary antipyretics in typhoid and other low fevers, on account of their depressing effects; and as I have often had good results from sponge-baths, when not employing the general bath, I continued to look around for some agent to be applied to the general surface of the body that would have a marked effect in reducing temperature. In a case of pulmonary tuberculosis that Dr. J. Solis-Cohen and I saw together, he mentioned that he had succeeded in lowering the fever in tuberculous patients by the external application of guaiacol, and he spoke of several patients suffering with tuberculous laryngitis in whom, after the application of this agent to the throat and front of the chest, the reduction was marked, confirming thus the observa-

[1] From a lecture delivered at the Pennsylvania Hospital, January 13, 1894.

tions made by Bard in tuberculous cases. So far as I can learn, the powerful antipyretic effect of guaiacol when applied to the skin was first pointed out by Sciolla.[1] Bard's observations on tuberculous patients followed,[2] and were soon corroborated by Lannois. The treatment is not regarded as suitable when there are cavities in the lungs, or in cases of pneumonic consolidation, though I believe it has been used in a few cases of pneumonia. Ordinarily from one to three grams were used for each application, rubbed over the affected area in the lungs, or painted on the thigh or the back, the part being covered with an impermeable dressing.

Upon reflection on these observations, it occurred to me: Why not make use of guaiacol in systemic fevers in the same way? So for the last two months, with the aid of my very efficient resident physician, Dr. Branson, I have been engaged in making observations upon fever cases, especially typhoid-fever cases, the results of which I will now report to you. I may say that the investigation was begun without preconceptions. The results were positive and conclusive.

The temperature-chart of the case before you (Chart No. I) is shown herewith. Observe the drop from 105.4° to 98.6° on the night that he was admitted. After the high temperature had been recorded thirty drops of guaiacol were painted upon the surface of the abdomen, in the right iliac region. The remedy was rubbed in for about fifteen minutes. The axillary temperature was then taken every fifteen minutes for two hours, and at periods of one hour afterward. The remedy was applied first at 6.15 P.M.; and at 9.45, three hours and a half later, you observe that the temperature had fallen to 98.6°, or nearly seven degrees, surely a tremendous reduction. The next rise was at midnight, when the temperature was 103.4°; therefore a permanent reduction of two degrees was obtained. At 1.30 A.M., the guaiacol was again applied, and one hour later the temperature was 102°; half an hour later it was 98.2°, and the patient had a slight chill. He has had, in all, sixteen of the treatments in seven days. Every one has been followed by a most distinct reduction in the fever. In all of them we notice that this reduction of the temperature is a slow one. We note, also, that the lessening of the fever-heat is not attended by any appreciable difference in the pulse, or by a difference of only a few beats. The reduction is not accompanied by any disturbance of the nervous system, but a chill happened three times in this case, when the temperature fell to 98°, the chilly sensations beginning when the temperature reached 101°. The chills were not very marked, however, and were what the patient describes as "dumb chills." As regards the effects of this agent upon the nervous system, I wish particularly to point to their absence. There was no increased debility, no delirium, no depression or sign of collapse, nor, indeed, any manifest disturbance of nerve-function.

I have dwelt in this case on the treatment of the symptom of high temperature by the local applications of guaiacol; let me state that this was everything in the way of treatment that was employed, except that whiskey, half an ounce every three hours, was given to sustain the circulation. For a short time, when pulmonary symptoms were present, ammonium carbonate was given. The general treatment, therefore, was the antipyretic one. It was exactly a case that ordinarily would have been treated by cold baths.

The temperature of the patient this morning is 102°; his tongue is moist and clean. I will prescribe for him eight grains of quinin a day and still administer the stimulant in the same amounts. We will also continue the liquid diet; but it will be unnecessary to resort to the local applications of guaiacol, unless the temperature should again show a tendency to rise to its former height.

I have many other cases illustrating the use of the same remedy, but I will not go into the details of the other cases. I would call your attention, however, to the temperature-records of a few of them. Here is the chart in the first case in which we used the remedy, one of typical typhoid fever (Chart No. II). It was a case marked by a good deal of delirium. You will see here the same decided drops after applying the remedy, though they are not so striking as in the other case, because the temperature was not so high. The temperature here was 104.4°, therefore distinctly a case of high temperature. In this case Dr. Branson reports that after three applications the patient had no more of the marked nervous symptoms that existed prior to the use of guaiacol; he had no tremor or other nervous phenomena, but it was particularly upon the delirium and upon the high temperature that the effects of the agent were most noticeable. In this case, also, the reduction of temperature was slow and its effects were extended over a long period. Sometimes there was no result for an hour, and then the reduction occurred gradually. This lessening of the fever-heat went on even to the normal, with no change in the pulse or respiration, no obvious change in the urine—in fact, no effects manifested except upon the temperature. and, as just stated, upon the delirium. Sweating occasionally happened, but was not liable to be great.

I will briefly refer to the chart in case No 3, merely to show that you may go too far with this powerful heat-reducing agent. This was one of our earlier cases. We applied forty drops, but with a

temperature not nearly so high as in the other cases. We reduced the bodily heat, it is true, but more than we intended, for we sent the temperature down to 97°. This taught us that the proper dose of the agent should rarely be above half a dram; and also that we must proportion the dose to the height of the temperature. In this instance, also, it is to be noted that no other effects were present—no effects upon the pulse, upon the respiration, or upon the nervous system, and no chill, in spite of the great reduction in the bodily temperature.

Encouraged by these results in typhoid fever, we have also been using guaiacol in pneumonia. To this I may here briefly refer, although it leads me away from the subject of this morning's discussion, which is the treatment of high temperature in typhoid and kindred fevers. I will say, however, that with a temperature of 104.4° in a case of pneumonia, while we failed to obtain the striking effects that we saw in typhoid, yet guaiacol reduced the temperature two degrees. There were no noticeable effects upon the rate of breathing, and no material reduction of the pulse. In a second case of pneumonia, which was approaching the period of crisis, when, however, there would naturally be a drop, we note a reduction of 3.5°.

I have given you the results of a series of clinical investigations, begun with the sole purpose of ascertaining the effect of remedies externally applied in lowering temperatures, and in the hope of finding something that will be effectual besides the cold bath. You will ask: What general statements can we make as to the plan of treatment by guaiacol? What is its applicability, and what are its advantages? Its general applicability is this: It will be of value in all those cases with high fever-temperature—I am now speaking particularly of typhoid and other febrile maladies, and not of pneumonia and inflammatory diseases—in which you would employ the cold-bath treatment if the conveniences were present or circumstances would permit. As you know, I am an advocate of the cold-water treatment, when there are attendants to carry it out properly; but it has its disadvantages. A very important objection to the cold-water treatment is the disturbance of the patient which it necessitates—the lifting him out of bed, the plunge into the water, and subsequent drying process—all this produces considerable perturbation, and in some cases may be followed by untoward results. There is another disadvantage of the bath, and one which has particularly attracted the attention of the French physicians; it is that when there is a tendency to severe diarrhea and to deep ulceration there is always a greater likelihood of intestinal hemorrhage when the patient is much moved. Therefore, when such a tendency exists, you would abstain from resorting to the cold-bath treatment; and it is in these cases that guaiacol will be found of special advantage, used in the manner mentioned. Moreover, it is to be preferred in all instances in which much moving or disturbing the patient is to be avoided.

You may ask: What is the relative promptness of action of the methods discussed? In this respect, I think, guaiacol is inferior to the cold bath. When, as in the case shown, the temperature is 105° or more, you will get more immediate and visible effects from the cold bath. This patient would have had a more speedy reduction of temperature if he had been put in a cold bath than he had from the remedy employed. I admit this. I would, however, call your attention to the fact that the reduction of temperature is more permanent; the fall occurs more slowly and it takes a much longer time for the temperature to rise again than it does after the bath, for we all know that if a patient with a temperature of 105° is put into the bath and his temperature recedes to 100°, at the end of a few hours a high temperature is likely to return, and we have to think of giving him another cold bath. In the element of permanency the cold bath is inferior to the treatment we have been discussing.

What are the objections to the guaiacol-treatment? One of the chief is its odor, which is decidedly unpleasant in the sick-room. We have endeavored to overcome this, and are still experimenting. We have tried bergamot, only to record failure; the odor of the guaiacol overcomes that of the bergamot. We have tried also Cologne-water and oil of sassafras; our best result is from the oil of cloves.

The mode of employing guaiacol is by rubbing it upon the skin of the abdomen or thigh with a camel's-hair brush, the selected area having been first prepared by washing with soap and water. The maximum dose in our investigations in fever cases was fifty drops; and from the effects witnessed I would advise that so large a dose should be rarely used. Thirty drops is about the average dose, although sixty were employed in one case of pneumonia. The guaiacol is to be rubbed in slowly; the surface need not be uncovered during this time, as it can be applied under the bed-clothing, and it is well to cover the surface with a piece of lint and waxed paper. The dose must be proportionate to the height of the fever. It would be proper with a temperature of 103°, not to exceed 20 minims at the first trial. In one instance of malarial fever in an anemic subject in the ward of one of my colleagues, an application of 30 drops when the temperature was 103.6° caused it to drop to 97°. The guaiacol may be also applied to the skin without rubbing it in, only covering the part with lint and waxed paper. The action is the same, though not

so rapid nor so perfect. The quickest way is to paint the guaiacol on the surface, then to rub it in with the hand. Five minutes are enough for the purpose. The local sensation is not unpleasant, being like that of menthol.

How does it act? Is it by absorption through the bronchial mucous membrane or by cutaneous absorption? I believe that its effects are produced by absorption by the skin and its entrance into the circulation by this channel; being carried to the heat-centers, it acts as an anti-thermic agent. It belongs to the series of wood-tar products, and it acts apparently without the depression that follows the use of antipyrin, phenacetin, and other remedies of this group of the coal-tar products. Moreover, though there is some action on the skin, the sweating is not nearly so great.

In conclusion, I would advise you to watch the urine, for in all cases of administration of medicines by the skin it is chiefly by the urine that the medicine escapes from the system. The urine is for the most part somewhat increased, but I can also say that in all of our cases in which we used the guaiacol there was no albumin in the urine, and no signs of kidney-irritation were detected.

I hope that you will not understand that I mean that you should treat all your fever-cases with guaiacol, to the exclusion of other treatment. I simply started out to tell you how to meet the high temperature when it is necessary to meet this symptom. This ought not to prevent you from attending to the other features of the malady. But I wished to call your attention markedly to a new plan of treatment which we have employed with results that are very encouraging.

A REPORT OF TWENTY-TWO ABDOMINAL SECTIONS IN GENERAL SURGERY.[1]

By W. B. ROGERS, M.D.,
OF MEMPHIS, TENN.;
PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN MEMPHIS HOSPITAL MEDICAL COLLEGE; CONSULTING AND VISITING SURGEON TO ST. JOSEPH'S HOSPITAL, ETC.

The following is a report of my operations on the abdominal viscera during the past year. I have included only those cases in which the abdominal wall has been traversed by the knife, and the peritoneal cavity thus exposed. All cases of suppurative appendicitis and other collections of pus in which the fluid was reached and evacuated without invading the uninfected peritoneum have been omitted. Those of you who have enjoyed operating in a well-regulated hospital can appreciate the advantages accruing to the operator over those obtained in what might be termed outside general surgery. In a hospital the operator has complete control of the case; in non-emergency cases the minute details of preparatory treatment can be carried out to his satisfaction, and he operates on a patient whose secretions are all in good condition. In emergency cases, such as have been most of those presented in this report, the saving of time by reason of convenience of arrangements and having everything at hand to meet complications arising during an operation, is an all-important element in the successful ending of an operation on the abdominal viscera. The thoroughness of an operation obtainable by reason of conveniences and reliable trained assistants cannot be overestimated. The complete control over the patient enables the operator to maintain perfect quietude, as well as carrying out in detail and with promptness the all-important after-treatment, both local and general; and, in my opinion, the after-treatment of a case of abdominal surgery requires as much care and skill as does the operation itself. For these reasons I have included only those cases operated on in my infirmary and St. Joseph's Hospital, because it is manifestly unjust to operator and operation to include those cases operated upon on the outside and under unfavorable surroundings.

A careful reading will show the critical condition that most of these cases had reached when the operation was undertaken, and it has been to careful nursing and close watching in the early hours of the after-treatment that more than one of the recoveries may be accredited. In evidence of the thoroughness of the aseptic and antiseptic details, in only one instance did fatal peritonitis arise after the operation, and that presented the features of traumatic peritonitis. One death (Case XXI) occurred on the eleventh day, from acute nephritis, without any intra-peritoneal inflammation or evidence of lesion of any other organ. Excluding those cases in which the intra-abdominal condition was irremediable by any operation, and Case XXI, in which death occurred from nephritis, it will be seen that there were nineteen operations with one death.

Case II represents two operations.

Case I. *Resection of the small intestine for gangrene; end-to-end anastomosis with the Murphy button.*—On Thursday, October 12, 1893, R. H., twenty years of age, jumped from a wagon to the ground. The jar caused the descent of a right inguinal hernia, to which he had been subject for several years. He had previously been able to reduce the hernia whenever it appeared, without the aid of a physician, but on this occasion he failed, and called his physician, who, without the aid of an anesthetic, and with very little effort, apparently succeeded by taxis in pressing the hernia back into the abdomen. The patient, however, continued to complain of pain extending from the inguinal canal toward the umbilicus. There was a slight fulness or induration at the site of the internal ring, but apparently this was within the abdominal cavity. The patient's general condition was nearly normal. During the next two days, calomel, salts and oil failed to act

[1] Read before the Southern Surgical and Gynecological Association, New Orleans, November 15, 1893.

on the bowels. So also did repeated enemata of large quantities of water fail to bring away fecal matter. The abdomen was gradually becoming distended and tympanitic, and when I saw the man, two days after the occurrence of the hernia, I found the belly greatly swollen, tympanitic, with marked tenderness from the umbilicus down to the inguinal canal on the right side. He was vomiting a dirty greenish-looking fluid, with distinctly fecal odor. The pulse and temperature were about normal. I invaginated the scrotum with my finger, carrying it well up into the inguinal canal, but was unable to feel the hernia there, though just above Poupart's ligament, and just under the internal ring, there remained a small induration, indistinctly felt by the reason of distention of the abdomen. I concluded that the hernia had either been reduced in its sac, or else that both had been well pressed up the inguinal canal, and between the peritoneum and wall proper. An operation was at once decided upon. An incision, three inches long, was made over the site of the appendix. At least a pint of blood-stained water escaped from the peritoneal cavity. Inserting my two fingers, I detected a constriction at the internal ring, and succeeded in drawing out eight inches of intestines. This I brought through the abdominal wound to the outer surface of the abdomen. The bowel was so congested at each extremity of the eight inches, where the encircling band had constricted it, that the peritoneum had given way, and gangrene was imminent. I immediately cut out ten inches of intestine, and made an end-to-end approximation by means of Murphy's button. All hemorrhage was arrested, the abdomen cleansed, and a drainage-tube so placed as to reach the bottom of the pelvis. The wound was closed with silk sutures, and the patient taken off the table with a pulse of 80. The reaction that night was pronounced, the temperature reaching 103°, but it fell promptly by morning to 99½°. The pulse from that time on did not go above 86, and the temperature ranged under 100°. Fifteen grains of calomel were given the night after the operation; ten grains more on the next day, and by means of oft-repeated large enemas the intestinal canal, at the end of sixty hours, was thoroughly emptied of all gas and fecal matter. The patient's general condition was good all of the ime after the operation, and he expressed himself ready at any time to get out of bed and go to work. His appetite remained good, and he is eating ordinary food. The drainage-tube was removed on the third day. The button was passed at the end of the seventh day. Thirty-two days have now elapsed, and his bowels are acting every day without medicine.

(The patient was presented for examination by the Fellows of the Association.)

CASE II. *Distended gall-bladder; cholecyst-enterostomy by Murphy's button.*—C. E., fifty-three years of age, of sedentary habits, had suffered more or less with dyspepsia for years. Six months before consultation he became very much jaundiced, and the liver was greatly enlarged. He had no fever; the pulse was feeble, 60 beats per minute. The man was emaciated to almost the last degree. There was great pain over the pyloric region, with tenderness all along the liver, which projected in a uniform line three inches and a half below the border of the ribs. At the anterior axillary line there was a distinct projection downward from the liver, reaching the anterior superior spinous process of the ilium. The case had been diagnosticated by several physicians as one of carcinoma of the liver. While the symptoms pointed strongly to such a condition, I was not willing to consent to the diagnosis without an operation. This growth had been rapid, and had even *overreached* the rapidity of growth characteristic of malignancy. I detected what I thought to be the rounded end of the gall-bladder projecting at the lowest point of the enlarged liver. An incision was made 2½ inches below the anterior extremity of the ninth rib, extending downward three inches. Upon entering the abdomen I found the liver greatly enlarged and very much congested. It was blue, and projecting at its lowest point was the gall-bladder. I succeeded in bringing the fundus of the gall-bladder in the incision, and opening it, evacuating fourteen ounces of bile. With a probe introduced into the gall-bladder, and my two fingers in the abdominal cavity, I was enabled to follow the cystic duct to the common duct, but no further. I examined with my two fingers the under surface of the liver, and found no signs of malignant disease. I tested the common duct to the duodenum, and could find neither gall-stone nor malignant growth, but the liver was so swollen that a stone in the common duct might easily have escaped touch.

The condition of the patient at this time admonished a rapid completion of the operation, so that I did not attempt a cholecyst-enterostomy, but sutured the gall-bladder to the anterior wall of the abdomen, hoping that with the use of liberal douches of hot water I might succeed in clearing out the common duct. The patient reacted slowly after the operation, but in a few days was out of all danger. The hot-water douching was tried, and every effort made to pass a probe along the common duct, but without success.

At the end of three weeks there was some gain in strength, the appetite was good, and the color had become nearly natural. The liver had receded beneath the ribs. In this state I allowed the man to return to his home to recuperate before undertaking a cholecyst-enterostomy.

The patient returned after three weeks, with the general condition slightly improved, but the absence of bile from his bowel seemed to have prevented his gaining in flesh. The prospect of improvement in the absence of bile was so unpromising that, although his condition was bad, in consultation it was deemed advisable to connect the gall-bladder and the bowel.

At the time of this operation I again explored the tract of the common duct, and felt two distinct enlargements, believed to be calculi. This case was not one for waste of time in efforts at removal of calculi from the common duct, so I hastily performed the cholecyst enterostomy, using the Murphy button. The case progressed favorably, the button coming away from the fistula in the abdomen on the seventh day. We had much trouble in keeping the food from escaping *via* the gall-bladder. Most of the bile passed into the bowel. The condition of the man for ten days was precarious indeed, but slowly improved, and he went to his home at the end of four weeks. There he gained about fifteen pounds in flesh, and was slowly but steadily improving until three months after the operation, when he was taken with diarrhea, soon becoming dysenteric, and died on the third day.

The operation, however, of gastro-enterostomy with the Murphy button proved entirely satisfactory, and so far as an operation was concerned is to be regarded as a success in this case.

CASE III. *Acute appendicitis.*—J. M., twenty-six years of age, a white male, was brought to my infirmary by Dr. Carmack, of Iuka, Miss., three days after the onset of an attack of acute appendicitis, which was marked by the usual symptoms. He had a pulse of 80, and a temperature of 100°; the abdomen was rather full, and a distinct lump could be felt at the site of the appendix, where there was a marked degree of sensitiveness to pressure; the bowels were acting well under cathartics. I made the usual incision, and found the head of the colon and a coil of intestine strongly bound together and to the wall of the pelvis, by inflammatory adhesions. These adhesions were quite strong for their age, and great care was necessary in separating them. They were all liberated and the appendix found tightly bound to the

colon, very much swollen and inflamed. It was tied and removed, and the wound packed lightly with gauze. The patient ten weeks after the operation was attending his duties as salesman.

CASE IV. *Empyema of the gall-bladder; cholecystotomy; forty-five calculi removed.*—Mrs. W., forty-three years of age, white, was seen in consultation with Dr. Lipscomb forty-eight hours after she was taken sick. She was suddenly seized with a pain, which she described as a cord around the base of her chest. There was great difficulty in breathing, and the pain extended down the right half of the abdomen, toward the pelvis. It was the time of her menses, but the flow after two days ceased abruptly five hours before she was taken sick, and this checking of the menses was naturally looked upon as playing a prominent part in the causation of this pain. She vomited a quantity of bile. The pulse was 80, and the temperature normal. An opiate was administered, followed at once by a full dose of calomel, and in two hours the patient had two large typical bilious actions, but her pain and vomiting of bile continued, while the tenderness in the region of the appendix increased. At the time of my first visit I found her with a temperature of 101.5°, the pulse 100; McBurney's point of tenderness was very pronounced; in fact the symptoms pointed quite strongly to a case of appendicitis. There was a distinct tumor, the size of the first, extending upward and outward from McBurney's point. It could be felt, but could not be handled, owing to the pain; I succeeded, however, in detecting some mobility of this mass and traced its outline upward toward the liver. While the symptoms pointed strongly toward appendicitis, and tenderness at McBurney's point was most pronounced, there were some things that led me to suspect a distended gall-bladder. First, the size of the tumor was too great to have been attained in forty-eight hours from appendicitis; secondly, an appendicitis producing a tumor or mass of adherent intestines of the size in this case, would have been accompanied by such a degree of inflammation surrounding the mass as would have bound this down and prevented any motion laterally; and lastly, the fact of the two actions of the bowel after the pain had begun so severely, together with this excessive vomiting of bile—all, I say, led me to doubt the existence of appendicitis and rather to attribute the enlargement to distention of the gall-bladder. The previous history told of numerous attacks of colic from five to eight years back, although in the past three years she had had no trouble of that kind. An operation was decided upon for the relief of whatever the trouble might be.

The patient was removed to my infirmary, and being placed under an anesthetic preparatory to the operation, the tumor could be mapped out as rising and falling with the diaphragm, could be traced upward, and could be moved laterally through a space of two inches. I was now confident that the case was one of acute empyema of the gall-bladder and I made the incision accordingly. The gall-bladder was found very much inflamed, and holding eight ounces of purulent matter, which was drawn off with an aspirator. A soft flat sponge was used to protect the cavity and an incision was made in the gall-bladder, and with a scoop and forceps I removed forty-five gall-stones, one the size of a filbert, the rest much smaller. There still remained one stone that blocked up the cystic duct. After considerable manipulation with the fingers in the abdomen and the forceps in the gall-bladder, I succeeded in crushing the stone and washing it out. The fundus of the gall-bladder was of a blue-black color and tore readily, and showed all evidences of approaching gangrene. The gangrenous point corresponded to the tender spot of McBurney on the abdomen. I removed the fundus of the bladder as far up as necessary and stitched the margins of the opening to the abdominal wall, making a biliary fistula The patient was put to bed in about the same condition she was in when placed on the table. She came from under the anesthetic complaining of great pain, thirst, and nausea. The abdomen was distended. In a few hours the pulse went up to 110, and the temperature to 101°. There was constant eructation of gas and some vomiting. The indications were clear that the bowels should be moved at once. Enemata, and calomel and soda by the mouth, were used freely. At the end of twenty-four hours her pulse was 150, respirations 8, and the pupils contracted to a pin-point; there were frequent retchings and belching, the abdomen greatly distended, and the condition a forlorn one. Having tried salts and calomel I now resorted to drop doses of croton-oil. The woman was twelve hours in this condition before we succeeded in getting the bowels moved. They acted seven times, when to our great satisfaction the patient had a pulse of 90, a temperature of 100°, respirations of 16, with the mind clear, and clamoring for some nourishment. Milk was cautiously administered once every hour, and the patient went on rapidly to recovery. There remains a fistula at the end of twelve weeks, but this is progressively contracting, and there is every evidence that bile is reaching the intestinal canal.

This case presented a number of interesting points in diagnosis, and after operation showed that in a few hours more the case would have been a hopeless one. Attention should be called to the absence of jaundice at this time; nor had she ever been so affected; this argues that the common duct had never been obstructed.

CASE V. *Acute recurring appendicitis.*—L. S., a male, thirty-six years of age, had a history of a severe attack of appendicitis three years before, and since that time a continued sense of uneasiness in the parts, and especially a sense of tension in the iliac region when standing erect. He was brought to my infirmary with a temperature of 102°, a pulse of 100, andwith a history of an acute attack of five days' standing. A slight tumor was detected upon palpation. The bowels had been thoroughly acted upon, so that an operation was performed at once. The abdominal cavity was opened over the appendix, which was found lying behind the cecum, and closely attached to it, as well as to the abdominal wall, by old adhesions. Circumscribed peritonitis was plainly evident over the cecum and adjacent intestines. The appendix was separated from the adhesions and removed. This patient recovered without any untoward symptoms, and in eight weeks resumed his usual vocation. The appendix was enlarged and thickened and showed evidences of chronic inflammation, though no ulcer or evidence of ulceration could be discerned. It contained muco-purulent matter. (*Dr. Winston.*)

CASE VI. *Empyema of the gall-bladder; three gall-stones removed.*—Mrs. C., thirty-two years of age, had a previous history of repeated attacks of gall-stone colic, the true nature of which attacks seemed never to have been suspected. She was brought to my infirmary suffering from a typical attack of gall-stone colic, with a tumor corresponding to a distended gall-bladder and which extended downward about four and one-half inches below the ribs. She was jaundiced and the abdomen was swollen and tender. The temperature was 102°, the pulse 100. Obstruction from gall-stones was evident, and I opened the abdomen through a vertical incision over the gall-bladder. I removed three stones, together with six ounces of bile mixed with pus. The gall-bladder was stitched to the anterior wall of the abdomen and gauze drainage arranged. The patient made an uninterrupted recovery. Within two months the fistula had healed and the patient was in perfect health. (*Dr. J. W. Gray.*)

CASE VII. *Carcinoma of the cecum.*—N. A. J., thirty-one years of age, male, white, much emaciated, with a pulse of

120, a temperature of 100.5°, appetite fairly good, bowels tending to diarrhea, was brought to my infirmary by Dr. Gladney. The patient had had an excellent physique and enjoyed the best of health until within six months, during which time there had been progressive and rapid loss of flesh to the extent of sixty-five lbs. In the right iliac fossa there was an indurated mass that had led to a suspicion of appendicitis. The enlargement corresponded in location to an adherent mass of the bowel, such as is frequently seen in appendicitis, but it was movable in each direction, and did not seem to be as closely bound to the posterior wall as is the case when the mass is formed by adherent coils of the intestine. It also felt hard and nodular. I expressed the opinion that the tumor was malignant, but inasmuch as there was some room for doubt an exploratory operation was performed. A three-inch incision through the abdominal parietes just over the tumor revealed a growth in the wall of the cecum. It was very hard and included at least six inches of the bowel. The mesenteric glands so far as they could be examined were enlarged and hardened. The great omentum was attached to the growth, and in this omentum a chain of enlarged lymphatic glands was plainly detected. The suspicion of malignancy being confirmed, and being satisfied that no benefit could be derived from an enterectomy, I removed about four inches of the omentum, including several lymphatic glands, each about the size of a filbert. The operation having been thoroughly aseptic in every detail, the wound closed, and on the tenth day the patient was taken to his home in the country apparently in better condition than he was on arrival here. A microscopic examination of the mesenteric glands proved the growth to be carcinomatous.

CASE VIII. *Chronic recurring appendicitis with perforations.*—C. McL., a male, thirty-seven years of age, with a history of repeated attacks of appendicitis, acute in character, reached my infirmary with a temperature of 103° and a pulse of 110. His general condition was very bad, the bowels being locked. (Six months before he had declined an operation which I had urged upon him during one of his attacks.) At this time, twelve days after the attack began, I found a tumor at the site of the appendix. The symptoms of general peritonitis were very prominent. There was doubt as to whether there might not be a general suppurative peritonitis. He was placed upon the table and the abdomen opened over the appendix. The intestines were found highly inflamed. There was a mass of adherent bowel just under the incision. Before separating the adhesions the field was walled off by sponges, and the coils of intestine were carefully separated, allowing two ounces of pus, with small particles of fecal matter, to escape on the sponges. The appendix was not sought for, but the wound was packed with gauze, and the patient recovered without any complicating symptoms. This was a case of perforative appendicitis, and although the patient recovered from this operation, I think it can be safely argued that he would have run much less risk if he had accepted the operation when proposed six months before, when there was probably no pus present. (*Dr. Rudisell.*)

CASE IX. *Abscess behind the cecum.*—J. L. H., male, white, thirty-four years of age, had been sick three months with typho-malarial fever, during the course of which an enlargement formed within the abdomen at the site of the appendix. In the course of time, coincidently with the subsidence of this enlargement, he passed from his bowel about a pint of pus. The diagnosis of appendicitis was offered and the patient brought to my infirmary. His pulse was 120, the temperature 100.5°, appetite absolutely wanting, prostration profound —making in fact a perfect picture of a man after an attack of typhoid fever. There was still a tumor at the site of the appendix, which was tender on pressure. After watching him and trying to build him up for ten days without being able to chronicle any success in the treatment, the abdomen was opened by an incision over the tumor. The appendix was found normal, but behind the peritoneum and behind the head of the colon could be distinctly felt a more or less fluctuating mass. The incision already made was carefully protected by sponges while another incision was made just above the outer portion of Poupart's ligament and the peritoneum carefully raised and followed up to behind the cecum, when the pus-cavity was opened and a teacupful of thick, yellow, curdy matter escaped. The probe detected the crest of the ilium and sacro-iliac junction to be eroded. The wound was packed with gauze, and the patient made a slow recovery without any symptoms of peritonitis, and in two months he was able to sit up, and eight months after the operation he had gained sixty pounds and was enjoying perfect health.

CASE X. *Incarcerated umbilical hernia.*—Mrs. T., forty-two years of age, the mother of a number of children, was referred by Dr. Crofford for incarcerated umbilical hernia. There was a hernial mass about the size of a child's fist, which was very painful upon manipulation and had been in existence for years. During the earlier days of its existence the woman had oftentimes reduced the hernia by gentle pressure, but for five or six years past she had been unable to reduce the size of the enlargement by any amount of pressure. The patient had a very large abdomen. She was admitted to my infirmary, and after a week's preparatory treatment I made an elliptic incision over the hernial mass, opened the sac, and after considerable difficulty succeeded in separating the adhesions between the sac and the hernia, which proved to be omental. I then cut away the excess of tissue in the abdominal wall, and closed the wound with silk sutures. Her recovery was not marked by any symptoms worthy of mention. She went home at the end of six weeks wearing a close-fitting abdominal bandage.

CASE XI. *Acute perforative appendicitis.*—J. H., male, white, thirty-eight years of age, presented himself about the tenth day after the onset of an acute attack of perforative appendicitis. His condition was exceedingly bad, so that I liberated six ounces of pus by Willard Parker's incision, and then thoroughly washed out the pus-sac. It was found that there were two fistulous tracts, one extending to the bottom of the pelvis, another leading to the site of the appendix. After four weeks' irrigation and drainage of these sinuses, the man was suddenly taken with fever, a temperature of 104°, and a pulse-rate of 140. There was obstinate constipation, general peritoneal pains, and so serious an aspect that it was deemed advisable to perform celiotomy in search of pus. The abdomen was opened just internal to the old incision and the fistulous tract followed down to the floor of the pelvis, several ounces of pent-up pus being liberated. The upper arm of the fistula was then drained and the remains of the appendix removed. The intestines all this time were kept back and walled off from infection by sponges. A glass drainage-tube was used, and for five days the patient's condition was very critical; at the end of this time, however, his bowels moved freely. His recovery was slow and the fistula remained for several months, but the last report was that it had nearly healed. No cause for the bowel-obstruction could be found other than peritonitis due to pent-up pus in the lower end of this fistula. Although a suppurating tract was made continuous with the peritoneal cavity, we succeeded in preventing general peritoneal infection.

CASE XII. *Herniotomy for strangulated inguinal hernia: the operation completed with view to radical cure.*—J. B., a male, forty-three years of age, was brought to my infirmary in November, 1892, by Dr. McDowell, of

Mississippi. The patient walked from the railway depot to the infirmary, although in great pain from a hernial protusion in the inguinal region. The mass was not large, but extended just into the scrotum; it had been down about forty hours, and was quite tender to touch. The patient's pulse was 90, and his temperature 100°. All signs of hernia were present, and, after administering the anesthetic, and with gentle taxis having failed to reduce the hernia, I performed herniotomy. I found an old hernial sac which contained a loop of intestine very much discolored, but its peritoneal covering had not lost its luster. The inguinal canal was laid open, the bowel returned to the abdomen, and the McBurney operation for the radical cure of hernia carried out in detail. The patient's bowels moved that night, and the only trouble was in keeping him confined to bed during the eight weeks he remained with me. The operation has thus far (eleven months) proved a cure. The man is a farmer, and is doing his work as usual. This was a case in which prolonged efforts at taxis had failed, and at the time I saw it taxis was dangerous.

Case XIII. *Perforative appendicitis.*—J. D. S., male, white, thirty-eight years of age, presented a history very much like that of Case X. There had been an attack of peritonitis and a large collection of pus in the right iliac fossa. The fossa I opened by an incision just above the outer part of Poupart's ligament. The sac being washed out I could pass a probe upward and backward nine inches, following the posterior wall of the abdomen, as nearly as I could estimate it, almost to the pancreas. The liberation of this pus was followed by a rapid improvement in health, but the fistula still remained, and about every four weeks an accumulation of pus at the upper end of the fistula would give rise to grave systemic symptoms, with a temperature of 103°, a pulse of 140, and acute diarrhea. Every effort was made to ward off these attacks and keep the fistula well drained, but without effect. I was not able to say what was the first cause of the formation of pus; I am strongly of the belief that it was appendicitis, and that the pus burrowed upward and backward toward the diaphragm. Five months ago, during the height of one of the attacks of peritonitis caused by retention of pus, while his temperature was 103°, I opened the abdomen by an incision four inches in length just external to the right linea semilunaris. When the cavity was reached we found a collection of pus lying on the posterior wall of the abdomen behind the peritoneum, consequently behind the ascending colon. The intestines were walled off and the sinus followed for a distance of six inches. The fluid that escaped was of a dirty-brown color, purulent in character, and exceedingly offensive. The sac was thoroughly irrigated and packed with gauze. The patient's temperature fell rapidly, and the next day he was apparently well. His bowels moved regularly. All abdominal symptoms disappeared, the wound did well, and he gradually regained strength, and a few weeks ago resumed his work as an accountant.

Case XIV. *Chronic appendicitis; abnormally located kidney complicating the diagnosis.*—J. C., male, white, twenty-three of age, was brought to me by Dr. Mayfield. There was a history of bowel-trouble with a distinct tumor in the region of the appendix, which was very tender on pressure. His temperature was 102°, his pulse 100. He was very anemic, and had lost much flesh. The history of the case showed that there had been an acute attack of inflammation at the head of the colon, with the discharge of a quantity of pus by the rectum, and varying degrees of poor health extending over the six months past. There were some points about the feeling of this tumor at the site of the appendix that made one hesitate in pronouncing it an inflammatory mass; however, an exploratory operation was decided upon. The incision was made over the site of the appendix. The tumor was found to be a misplaced kidney, lying one-half within and one-half without the true pelvis. It was apparently healthy. The appendix itself showed slight inflammation of the peritoneal surface. Its walls were thickened and hardened; its general contour irregular and bulging at points. Its extremity was greatly enlarged, and upon removal was found to contain pus. Gauze drainage was used in this case. After ten days the fever had ceased, but there was a very slow recovery. The man is to-day, ten months afterward, in good health. This was another case of the catarrhal form of appendicitis complicated in diagnosis by the presence of an abnormally located kidney.

Case XV. *Acute perforative appendicitis.*—E. F. T., thirty-seven years of age, male, white, presented the characteristics of an acute perforative appendicitis. The attack came on without warning and without any previous attacks, the man having retired the night before, as he believed, in excellent health. I saw him with a pulse of 120 and a temperature of 102° sixty hours after the attack began. There was general abdominal tenderness, with the McBurney point especially well marked. The man was removed at once to the infirmary and the abdomen opened at the site of the appendix. The small intestine and head of colon were matted together by inflammatory adhesions. These were carefully separated, liberating about two ounces of pus with an admixture of fecal matter. The appendix was perforated at its base by an ulcer which included three-quarters of its circumference. Plainly speaking, a slough had occurred in the appendix near the base and the remaining portion was bordering on gangrene. Great care was taken to prevent contamination of the unaffected peritoneum. The appendix was ligated, removed, and the abdomen then thoroughly flushed with hot water. In this case gauze drainage was relied on, and the patient made a rapid and complete recovery. This was a case of perforative, or what we might almost term a gangrenous form of appendicitis, a case in which a very few more hours' delay would have allowed the case to get beyond the reach of surgical aid.

Case XVI. *Chronic appendicitis, producing relapsing dysentery.*—J. G., male, twenty-four years of age, had a history of six months' illness and a loss of thirty pounds in weight. During the illness all of his symptoms pertained to the bowels. It was a case of relapsing dysentery. He was removed to the infirmary with a temperature of 103°, and a pulse of 102. All of his pain was complained of on the *left* side of the abdomen near the iliac crest. Careful palpation detected a small tumor at the site of the appendix, on pressing which pain was produced on the *opposite* side. The usual incision for removing the appendix was made. The appendix, six and one-half inches in length, was found closely attached to the external and posterior aspect of the cecum. It was necessary to tie off its mesentery with five ligatures. The appendix was then ligated and removed. The head of the colon was found greatly inflamed, and the glands in the meso-colon and mesentery adjacent to the appendix were as large as chestnuts. Gauze drainage was employed in this case. The patient recovered without any symptoms complicating his case. At the end of two weeks he was able to sit up. On section, the appendix was found greatly thickened. There were no well-defined ulcers to be detected on its inner surface, though it contained a small quantity of pus. From the appearance of the head of the colon there was no question but that there were numerous ulcers throughout that part of the bowel.

Case XVII. *Chronic relapsing appendicitis.*—J. M., thirty-seven years of age, male, white, had been in poor health for a year and a half, with repeated attacks of bowel-trouble, accompanied by fever and other evidences of peritonitis; on several occasions his condition had

been quite critical. The diagnosis of chronic appendicitis was made, although no tumor could be felt. The operation was performed at the onset of a well-pronounced attack. The appendix, greatly enlarged, its walls greatly thickened, was found lying within the true pelvis, attached to the posterior wall on the right side, and completely cornered by an adherent coil of small intestine. Localized peritonitis existed, but there was no evidence of a perforation ever having taken place. The appendix was freed from all adhesions (by a ligature applied close to its base), and removed, the ligature being cut short. Although there was no pus seen in connection with the operation, it was deemed safest to employ gauze drainage. The man made an excellent recovery and has since enjoyed perfect health. The appendix in this case, upon section, showed five superficial ulcers on its mucous aspect. These ulcers did not extend through the mucous membrane. The case should properly be classed as one of catarrhal appendicitis, in which adhesions had taken place during some previous acute exacerbations, and continued to give rise to the trouble in the peritoneum.

CASE XVIII. *Empyema of the gall-bladder; one gall-stone.*—Mrs. P., fifty-eight years of age, with repeated attacks of colic during the period of seven years, was very much emaciated, with marked jaundice, dyspeptic, presented a tumor corresponding in outline and symptoms to an enlarged gall-bladder. Her condition was then fairly good, but she declined an operation for gall-stones, and after repeated doses of sweet-oil the tumor greatly subsided, though no gall-stones passed. In spite of all my entreaties to undergo the operation, she declined, and went home. She returned two months later with a small tumor at the site of the gall-bladder, with a temperature of 104°, a pulse of 130, completely prostrated, and with a history of a very severe chill every day for a week. Her condition was not such as would warrant an operation with any hope of recovery. I opposed an operation in her then exhausted condition. I did not believe there was any malaria in these daily chills; nevertheless I gave her quinin for forty-eight hours with a return of the chills at the end of each twenty-four hours. She came for the operation of cholelithotomy. I explained to her and the family what little hope there was of her surviving the operation, but they still insisted on giving her the chance, however slender that might be. I did not desire to shirk any responsibility, and knowing that the patient would die without the operation, and that operation was the only chance, I yielded to their solicitations, opened the gall-bladder and removed the stone. The peritoneum was highly inflamed as far as could be examined. The patient survived the operation only twenty-four hours, during which time she reacted well, was thoroughly conscious, and took nourishment freely. Her pulse and temperature both led us to hope she was improving, but she suddenly grew worse at the time for her daily chill, and passed away.

CASE XIX. *Enterectomy; lateral anastomosis.*—Mrs. B., twenty-four years of age, white, came to my infirmary in the last stages of what proved to be tuberculosis of the intestine. I had seen her two years before, after she had had a slight pulmonary hemorrhage. Careful stethoscopic examination had failed to locate any tuberculous patch. I had advised her to seek a climate better suited to one threatened with tuberculosis. One year ago I saw her in an attack of dysentery, which was controlled after several days of treatment by the usual remedies, calomel, opium, and ipecac. On the occasion of my last visit I left her with the promise from her that she would let me see her again in a few weeks to examine the site of the vermiform appendix, which location had during this spell been the site of most of her pain. A year elapsed before I saw her, which was on the occasion of her being brought to my infirmary, the mere shadow of a woman. There was a distinct enlargement at the head of the colon. She had had a long spell of dysenteric diarrhea, and had been in bed four months with fever, sweats, and rigors. Her physician had strongly suspected appendicitis, and had advised operative treatment. In consultation with Dr. Henning, her physician, I could not advise surgical interference, from the fact that the patient's condition did not promise that she would survive the operation. She and the family, however, pleaded so strongly that something should be done that I finally consented to an exploration, with the hope that the trouble was appendicitis. Upon opening the abdomen we found adhesions between the great omentum and the small intestine at the head of the colon. In separating these adhesions ever so carefully four or five holes were torn into the cecum; I could then make out about four inches of the cecum and two inches of the small intestine to be greatly thickened, and from the numerous small nodular patches on the outer surface my diagnosis was tuberculosis of the bowel. The patient's condition was desperate, but with the torn bowel, and with her request that "we should do something, remove everything in sight," I performed enterectomy, removing about four inches of the small intestine and six inches of the colon. A lateral enterocolostomy by means of Senn's plates was done. The general cavity was during the operation protected from infection by sponges. The patient put to bed, but I hardly expected her to live more than a few hours. Contrary to all expectations she lived four days and a half. Her bowels acted voluntarily three times after the second day. The gauze dressings on being taken off showed a slight fecal fistula. There was no evidence of acute peritonitis excited by the operation, though I doubt whether the patient had sufficient vitality for such a condition to be kindled up. She died from the original condition for which the operation was done, and not from the operation.

CASE XX. *Cyst of the broad ligament; pyosalpinx.*—Mrs. L., thirty-seven years of age, white, had been in poor general health, and had had fever, with much prostration. On the left side of the uterus there was a tumor the size of an infant's head. The tumor was painless, but by its presence pressed the womb against the right wall of the pelvis, where on bimanual exploration the symptoms pointed strongly to salpingitis. After five or six days of preparatory treatment celiotomy was performed, and the tumor, which proved to be a cyst of broad ligament, was removed. Both tubes and ovaries were removed, because on the right side there proved to be pyosalpinx. The operation was completed rapidly; a glass drainage-tube was employed because of much oozing, due to the separation of the adhesions on the right side. This patient did badly. Her pulse when she was taken from the table was 84, but rose steadily until the third day, when it was 140, with other symptoms of traumatic peritonitis. She died at the end of the fifth day.

CASE XXI. *Chronic appendicitis.*—Miss B., thirty-one years of age, had the following history: Seven months ago she had an attack of appendicitis, in which there was a formation of pus, which was evacuated by an incision two inches behind the anterior superior spinous process just over the crest of the ilium. She improved a good deal, but was not well, and after the end of four months had another slight attack, though no pus seemed to have formed; two months later, and one month before coming to me, there was a return of the pain in the iliac region of the right side, with fever, quick pulse, loose bowels, and much prostration. This condition continued until I saw her, when I diagnosticated appendicitis, based upon the tenderness over the appendix-site. The remaining portion of the abdomen could be palpated without causing complaint. Her pulse was 90, and the even-

ing temperature about 100°. The abdomen was opened over the appendix, which was found rather behind the head of the colon to which it was adherent, as well as the iliac fossa. The distal end was found attached to the wall of the abdomen at the crest of the ilium, corresponding to a cicatrix seen on the skin where the pus had been evacuated five months before. With my finger I succeeded in enucleating the end of the appendix from this iliac attachment, and separating it from its other adhesions I tied it off. Gauze drainage was used, and the patient was put to bed in excellent condition. The usual nausea of the anesthetic did not wear off, but continued through thirty-six hours. The pulse ranged from 70 to 80, the temperature from 98.5° to 100°. At the end of forty-eight hours the bowels were moved by enema, and salts acted a few hours later. There was no abdominal tenderness, no distention. The bowels continued to act freely from that time on; nor did any symptoms of peritonitis present themselves. On the third day after the operation the kidneys suddenly ceased to secrete urine, and for forty-one hours not one drop entered the bladder; then there were a few drams secreted, gradually increasing in the next four days at the rate of thirty-two drams in twenty-four hours. The urine was hemorrhagic, and contained both pus and tube-casts. The woman died of uremia on the tenth day, without one untoward symptom referable to the abdomen. Chloroform was the anesthetic used. The time of operation was thirty minutes; the room was carefully watched, and there was no exposure to cold. The urine had been carefully examined and found normal three weeks before the operation.

THE SYSTEMATIC QUALITATIVE ANALYSIS OF THE CONTENTS OF THE STOMACH.

By A. L. BENEDICT, A.M., M.D.,
of Buffalo, N. Y.

The accompanying tables are presented, not as containing anything new in the department of gastric chemistry, but with the hope that they may facilitate systematic investigation. The preliminary step in the study of gastric digestion is the administration of a test-meal. In making a series of examinations in a given case, it is well to vary the bill of fare, but the typical test-meal that will be found most generally available is the following: A tender chop or beefsteak, well broiled but not dried; a slice of home-made bread, two or three days old, with butter; a glassful of water. This meal contains albuminoids, hydrated starches, and fatty hydrocarbons. The exact amount eaten is not important; in fact it is best to let each patient take what he would consider an average light meal. From an hour to an hour and a half after eating, from fifty to a hundred cubic centimeters of the stomach-contents should be removed through a tube, undiluted if possible, filtered through absorbent cotton or filter-paper, and the tests should be applied to the clear liquid thus obtained. To prevent further digestion outside the body, the liquid should be kept cold; in fact it is best to examine it immediately.

The reaction is determined by litmus paper. A marked alkaline reaction is scarcely possible under ordinary circumstances. It would be expected after a copious hemorrhage into the stomach, or if much bile had entered through the pylorus. The reaction of the resting stomach several hours after a meal is neutral or nearly so. In examining under the conditions assumed, an hour or an hour and a half after the test-meal, the reaction will almost invariably be found acid. The acidity may be due to hydrochloric, lactic, acetic, or butyric acid, or to acid lactates or phosphates. Many aniline dyes change color with free acids, but not with acid salts. The behavior of methyl-violet, Congo-red, and tropeolin 00, with various acids, is given in a separate table. In the absence of the color-change we may certainly argue the lack of the normal hydrochloric acid of the gastric juice, which should be present in its greatest proportion about one hour and a half after the meal. The other acids mentioned represent respectively the chemic decomposition of albuminoids (especially of milk-foods), carbohydrates, and fats. If these acids persist an hour or more after the test-meal we may suspect them to be due to fermentation, and should then examine the gastric contents microscopically for bacteria and fungi, these being normally destroyed or held in check by the antiseptic power of hydrochloric acid. It is rare that the acidity of the stomach-contents at the time of the examination is due to acid salts alone, for the absence of hydrochloric acid favors the formation of one or more of the organic acids.

It will be noted that we have two quite dissimilar solutions that give the same test with hydrochloric acid. The same reaction occurs with other mineral acids which cannot be present in the stomach except by medication. The resorcin-solution is more stable than the solution of phloroglucin-vanillin, but not quite so sensitive. However, either will indicate the presence of one part of hydrochloric acid in twenty thousand (about one-tenth the normal proportion).

Lactic acids and lactates give the same reaction with ferric chlorid, but fortunately both have the same significance. The strictly chemic tests for acetic and butyric acids are inconvenient, and the odors are sufficiently characteristic.

Carbohydrates are converted into glucose by the ptyalin of the saliva, and by the amylopsin of the the pancreatic juice, the former acting on cooked starches, the latter on all carbohydrates. The test-meal contains only cooked starch in moderate amount, and, as the absorption of glucose is normally rapid, the carbohydrates should have disappeared entirely in an hour or an hour and a half after the meal. In case large quantities of starchy food, or even small amounts of raw starch, have been taken, the iodin-test will be found later—in

ACTION OF ACID AND OTHER SOLUTIONS ON ANILINE DYES.

Solution.	Methyl-violet.	Congo-red.	Tropeolin 0 0.	Aniline-orange.
HCl	Yellowish-brown, yellow, green, blue as strength of acid is decreased.	Blue.	Magenta.	No change.
$HC_2H_3O_2$ . . .	Blue with purple tint.	"	No change.	
Butyric acid .	Blue.	Dirty purplish-blue.	" "	
Lactic acid . .	"	Blue.	Similar to HCl, but less marked.	
HNO_3	Same as HCl.	Same as HCl.	Same as HCl.	
H_2SO_4				
$H_2C_2O_4$	Blue.	Blue.	Suggestion of pink.	
HI	Blue with slight purple tint.	"	No change.	
Picro-nitric ac	" " " " "	Brownish.	" "	
C_6H_5OH . . .	Blue transparency, unchanged reflection.	Slight change of shade.	Slightly lighter shade.	Not tried.
H_3BO_3	No change.	Blue.	No change.	
Tannic acid .	" "	Slight brownish shade.	" "	
NaCl neutral .	" "	Not tried.	Not tried.	
Fresh urine . .	" "			

the latter event until the stomach has completely emptied itself.

Chemists are unanimous in condemning the reduction-test for glucose as inaccurate in the presence of albumin. For clinical purposes this objection does not seem to hold good. Simply for the sake of economizing time, it is well to add the stomach-contents in a layer above the copper solution. The formation of a reddish-violet ring in the cold indicates the presence of propeptone or peptone. The tube may then be heated in order to test for sugar.

STOMACH-CONTENTS.

Reaction

Alkaline.	Abnormal.
Neutral.	Digestion complete, several hours after meal.
Acid, free.	Color change with aniline dyes.
" salts.	Color not changed.

HCl.

R.—Resorcini	5	or	R.—Phloroglucin	2
Sacchari albi	3		Vanillin	1
Aquam ad	100		Alcohol	30

Add 5 drops of reagent to 3 of stomach-contents. Evaporate in porcelain capsule. Crimson tint at drying edge = free HCl. Maximum ½–1 hour after meal.

Lactic acid. lactates.

R.—Tr. ferri chlor.	. .	0.10	Amethyst solution.
Ac. carbolici	. . .	0.40	
Aquam	. . . ad	10 00	

Add stomach-contents guttatim to 1 cm. of reagent in test-tube. Yellow color = lactic acid or lactates. Abnormal after 1 hour after meal.

Acetic acid. Odor of vinegar.
Butyric acid. " " rancid butter.
} Abnormal after 1 hour after meal.

Carbohydrates.

Starch. $C_6H_{10}O_5$

R.—I	. . . . .		1
KI	. . . . .		10
H_2O	. . . .	ad	200

Add 1 drop to filtered stomach-contents. Violet to blackish-blue color = starch. Abnormal after 1 hour after meal if test-meal contains only cooked starch. Raw starch normally present in unfiltered stomach-contents several hours after meal.

Sugar. $C_6H_{12}O_6$

R.—Cupri sulph.	. . .		10
Glycerini	. .	ad	100

Add gtt. ij to ½ c.c. of liquor potassæ. Shake till a uniform deep blue is produced.

Add in ring above reagent in test-tube a few drops of stomach-contents. Reddish-violet band in cold = propeptone or peptone. See below.

Heat. Reddish-yellow ppt. = sugar. Abnormal after 1 hour after meal.

Albuminoids.

Filtered stomach-contents + heat. Ppt = albumin or syntonin. Abnormal after 1 hour after meal. Filter to remove all traces of albumin and syntonin.

Filtrate No. 2 in ring above cold HNO_3. Ppt. = propeptone. Filtrate No. 3 removed by pipet.

Filtrate No. 3 + tannic-acid solution. Ppt. = peptone. Peptone should be in excess of propeptone, 1 hour after meal.

The tests here selected for albuminoids must be followed in order, or incorrect results will be reached. It will be noted that the same approximate limit of an hour is adopted for the completion of the preliminary stage of digestion. Albumin and syntonin should not be found much, if at all, after this period. Boas has demonstrated that propeptone is absent in the digestion of meat, but present in the digestion of plant-albumin and egg-albumin. Most of the proteid food in the test-meal is derived from meat, a little from wheat, and hence we must expect to find a very moderate amount of propeptone and a considerable precipitate in the final treatment with the tannic-acid solution. For convenience, the liquid designated "Filtrate No. 3," is removed by the pipet from above the ring of precipitated propeptone, instead of by ordinary filtration.

All the intricacies of gastric chemic analysis have manifestly not been alluded to in this schedule of examination. On the contrary, only the simplest and most necessary routine has been laid down.

The Affinity between Sectarianism and Quackery.—In the face of the universal condemnation of the methods of the so-called "Amick Consumption Cure" it seems entirely fitting that a sectarian publication (the *Physio-Medical Journal*) should rally to the support of this well exploited nostrum. This exhibition is but another instance of the close affinity that exists between sectarianism and outright quackery. For aught we know the words of commendation may be well paid for at so many dollars per inch of space, but the article of which we speak appears in the midst of regular reading matter.

CLINICAL MEMORANDA.

A CASE OF FIBRO-CYSTIC MYOMA REMOVED AT THE THIRD CELIOTOMY.[1]

By GEORGE RYERSON FOWLER, M.D.,
SURGEON TO ST. MARY'S HOSPITAL, AND TO THE METHODIST EPISCOPAL HOSPITAL, BROOKLYN, N. Y.

I. L. M. B., twenty-six years of age, single, a native of the West Indies, referred to me by Dr. J. S. King, of this city, was admitted to the Methodist Episcopal Hospital, March 3, 1890, with the following history: Four years prior to admission she noticed a swelling in the left iliac region. Prior to this there had been some menstrual disturbances, consisting mainly of amenorrhea. Eight months after the discovery of the tumor, and three years and four months before she came under my observation, a well-known and skilful surgeon of Kingston, Jamaica, W. I., attempted the removal of the tumor by celiotomy. The connections of the tumor were so extensive that the attempt at its enucleation was abandoned, and the abdomen closed. The patient made a good recovery from the operation. The tumor, however, continued to increase in size, and her general health failed notably.

Six months before admission, she suffered from an attack of general peritonitis, from which she recovered but slowly.

Upon admission, a large tumor of pelvic origin was found to be present, reaching to the ensiform cartilage, and extending laterally so as to occupy almost the entire anterior abdominal and pelvic regions, including both hypogastric and inguinal regions. It was found to be but very slightly movable. A semi-fluctuating area to the left of the median line gave the impression of a cystic portion of the tumor.

March 10th, an exploratory celiotomy by median incision exposed the tumor. The incision of the previous celiotomy had left a median scar, through which the present incision was made. Examination of the tumor now disclosed the fact that the most extensive adhesions, both visceral and parietal, were present. The omentum, transverse colon, and ileum, were all attached to the growth by adhesions, in which were seen ramifying vessels as large as the radial artery. In addition, the adhesions to the lateral pelvic wall and deeper pelvic structures were such as to effectually prevent its successful enucleation. In an attempt to investigate its intestinal connections, a loop of the ileum was opened; a Lembert suture was immediately introduced.

The fluctuating portion of the growth was brought to correspond with the abdominal incision and there sutured for a distance of about three inches. The remainder of the abdominal wound was then closed and dressed, and the patient put to bed. She rallied well from the operation, and, after firm union of the peritoneal surfaces had taken place, the cystic portion was opened by means of the thermo-cautery. The cyst-wall was at least an inch in thickness.

The cyst discharged at first a semi-transparent straw-colored fluid. Within a few days, however, this began to be mixed with débris from the tumor itself. Almost constant irrigation of the interior of the cyst was necessary to hold in check the constantly threatening, and, in spite of every care, occasionally developing septic condition of the parts. This continued for seven months, during which the patient's condition oscillated between improvement and loss of ground gained. She finally left the hospital, with the tumor about one-third less than its original size, and a sinus discharging, but which was kept clean by irrigating with hydronaphthol solution, iodin water, etc.

In January of 1893, the patient again visited this country, and Dr. King bought her to my office for examination. It was then found that the tumor had still further decreased in size, and seemed to be freely movable in all directions. A sinus, which, however, discharged but comparatively little, was still present. I expressed the opinion that the growth could be removed, and advised the woman to again enter the hospital for that purpose. This she consented to do.

On February 4th she underwent the third celiotomy. As a precautionary measure, the sinus and remains of the cyst-cavity were thoroughly washed out with a mercuric chlorid solution, and the opening closed by folding over it and suturing the adjacent abdominal wall. An elliptic incision was made so as to include the mouth of the sinus, the cicatricial tissue resulting from the former operations, and the entire thickness of the abdominal wall. The omentum was found to be extensively adherent to the abdominal wall and to the anterior surface of the tumor as well. So extensive were these adhesions that it was decided to remove a portion of the omentum with the growth. This was, therefore, carefully tied in sections with catgut, and the tumor freed in front in this manner. The lateral attachments of the tumor were found to include both broad ligaments, and portions of the latter were tied off with silk ligatures; the attachments to the uterus were easily separated, although the growth sprang from this organ. The adhesions previously existing between the growths and the transverse colon and the small intestines had entirely disappeared. The abdominal wound was closed by means of silkworm-gut and the crossed suture. The silk ligatures were led out of the lower angle of the wound.

The patient rallied well from the operation, and the case pursued a typically aseptic course. The silk ligatures from the stumps of the ligated broad ligaments came away on the sixteenth day following the operation.

The tumor removed is about the size of a child's head at birth, and consists of a fibro cystic growth. The remains of the cyst-cavity are plainly visible. The latter extended through nearly its entire antero-posterior diameter; but a very thin wall separated it posteriorly from the peritoneal cavity.

ESOPHAGOTOMY FOR THE REMOVAL OF A BUCKEYE-NUT.

By WILLIAM D. HAMILTON, M.D.,
OF COLUMBUS, OHIO.

On the evening of September 2, 1893, I saw an inmate of the Central Ohio Insane Asylum, in consultation with the members of the house staff. The patient, Levis S., twenty-four years of age, who had never been up to the average in intelligence, was a strong convalescent from mental disease. He had tried to swallow a green buck-

eye four hours previously. His sufferings brought him to the attention of the physicians in charge, to whom he related the facts.

An esophageal bougie was introduced by Dr. George Stockton, meeting an obstacle in the gullet. The posture of the man's head and neck was such as to relax the muscles in front. The chin was somewhat depressed toward the sternum. There were gagging, ineffectual attempts to vomit, and discharge of mucus, blood, and saliva. Efforts to swallow water were painful and futile. The patient was hoarse and there was some dyspnea.

A bougie, repeatedly inserted, met a firm substance, seven and a half inches from the incisor teeth. The neck was short and muscular and the thyroid gland was large. Deep palpation with the fingers through the cervical tissues against the spine proved nothing definite. In a thin subject the foreign body could probably have been outlined. The smoothness and fixity of the mass were evident. The use of the esophageal forceps through the mouth offered no chance of extraction; while propulsion of the body was impracticable and hazardous. An exploratory esophagotomy was advised. The man was etherized the following morning at the Mount Carmel Hospital in the presence of Drs. Stockton, Deischle, and Lindsay. An incision was made, three and a half inches in length, along the inner edge of the left sterno-mastoid muscle, the center being opposite the cricoid cartilage. The omo-hyoid muscle was then drawn upward, out of the way.

The sheath of the great vessels was exposed, and these were pulled away from the median line, with the overlying muscle, by means of a retractor. The trachea and thyroid gland were likewise drawn inward to give more room. At the bottom of the cut a lump could be felt with the finger. Incising the distended gullet at this point, a yellowish-white substance could be seen. The nut was soon pried out with a director. Its greatest diameter was about one inch. Two or three small vessels were tied. The wound in the esophagus was closed with a few catgut stitches, which did not enter the mucosa. Their insertion would have been easier before extracting the foreign body. The esophageal wall was at that time more accessible. A small pledget of iodoform-gauze was left in the lower angle of the wound. The unoccupied portion of it was closed with silk sutures.

Dr. Stockton fed the patient through a stomach-tube for three weeks. The instrument was carried in through the nostril. The wound was dressed on the third day, and the drainage-gauze was renewed. Some leakage and suppuration had taken place. A solution of boric acid (gr. x to water, ℥j) was used as a drink (Southam). The patient left the hospital on the ninth day, with the wound partly healed. After his return to the asylum, daily cleansing with hydrogen dioxid was ordered and the usual dressings were employed. Soft food was given by the mouth at the end of the third week from the operation. On October 25th the man was permitted to eat more substantial food. His neck was not wholly sound until November 5th; since this time no dietary restrictions have been necessary. The tardy process of repair was due in some degree to the contused condition of the esophagus. The continuance of the artificial feeding may have had some effect in preventing the formation of a traumatic stricture. The man is now in excellent health.

SARCOMA OF TONSIL; EVULSION THROUGH THE MOUTH.[1]

BY J. SOLIS-COHEN, M.D.,
PROFESSOR OF LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

A SPINSTER, fifty-eight years of age, was recently brought to me in consultation concerning a tumor of the tonsil which was stated to have been of some three and a half years' duration, and to have enlarged much more rapidly during the last six months than during the previous three years. The morbid mass was about the size of a small hen's egg, and was almost entirely covered by a distended and adherent soft palate, a very small portion of the tonsil being exposed at the extreme inner surface. Of this mass the tonsil itself seemed of the size of a large walnut. The tumor extended conically quite up to and upon the surface of the hard palate; while its extreme circumference could not be delimited by the finger forced behind the soft and hard palate. There was no glandular involvement. There was no pain, and there had been no pain during the entire history of the growth. There was some dysphagia, and some impairment in voice and in articulation—all mechanic in character. Removal of the growth through the mouth was decided on. After the adherent palatine folds were detached from the surface of the tonsil to which they were adherent, a section of the tonsil was removed with cutting forceps. Histologic examination of this fragment having confirmed the diagnosis of sarcoma, evulsion of the growth was practised as follows:

The patient being in the sitting posture, the parts were benumbed with cocain solution. Then the soft palate was divided with the incandescent electric knife so as to expose the growth vertically, which was then removed partially by evulsion with the fingers, and partly in fragments with forceps. It was found to be adherent to the periosteum of the palatine process of the superior maxillary bone, and quite a large section of this periosteum was detached by torsion. There was considerable hemorrhage, which was readily arrested by compression. After the raw surfaces had been thoroughly scraped with the finger-nail, and freed from fragments and roughnesses, they were submitted to energetic friction with small pieces of sponge saturated with undiluted lactic acid; and were then left to themselves without stitching.

Severe pain in the ear of the corresponding side was complained of immediately after the operation, and it continued for some twelve or fifteen hours. Otherwise the patient was free from suffering and underwent a complete and rapid recovery from the operative procedure, the edges of the incision uniting as promptly as though they had been sutured.

It is to be expected that there may be recurrent or consecutive sarcoma in this case, as ensues in almost all cases of the kind. Nevertheless, there is a prospect that this may not take place, inasmuch as the patient was healthy, and free from any apparent glandular involvement.

[1] Report to the Section on Otology and Laryngology of the College of Physicians of Philadelphia, December 20, 1893.

HOSPITAL NOTE.

MULTIPLE DEVIATIONS OF BOTH LEGS IN A RHACHITIC CHILD; OSTEOTOMY OF FIVE BONES PERFORMED IN ONE SÉANCE; RECOVERY.[1]

BY CHARLES GREENE CUMSTON, B.M.S., M.D.,
OF BOSTON, MASS.;
STUDENT ASSOCIATE OF THE ROYAL ACADEMY OF MEDICINE IN IRELAND;
SURGICAL ASSISTANT AT THE BUTINI HOSPITAL, GENEVA, SWITZERLAND.

C. I., ten years of age, entered the Butini Hospital in November, 1890. The father had always been healthy. The mother had had nine children, of which the patient and a brother, fourteen years old, were the only ones living; one child died at the age of eight years, from suppurating glands in the neck; another at the age of three years, from pulmonary tuberculosis, while another, at the age of two and a half years, died in convulsions. The remaining four children were stillborn. The mother's health has always been quite good until the birth of her last child (stillborn), about three years ago, which has left her an invalid, the disease probably being of a nervous nature, affecting the legs; the patellar reflexes are very much exaggerated, especially in the right leg, with great loss of strength in both limbs.

The patient, a little girl, was well developed at birth; she could walk when fifteen months old, but did not speak until three years of age, when, after a very severe fright produced by a loud noise, she suddenly exclaimed "Mamma." From this day she continued to talk, but ceased entirely to walk or run. At the time of her fright her legs were perfectly straight and well formed. As the child could no longer walk, she remained in bed for a period of three years, and it was during this time that the legs commenced to deviate. For the three years preceding the operation, that is to say, since 1887, she did not remain constantly in bed, because her parents forced her to get up and walk with the aid of crutches. When about nine years of age she had a cold abscess on the arm, which was opened, and the patient then went to Cannes for the purpose of taking sea-baths, in order to complete the cure for the abscess. When she returned home, after a stay of three months, she was so much improved that she could walk a little without crutches. However, soon after, the legs became still more deformed, and the patient, even with crutches, walked with great difficulty, and the parents now decided to have something radical done.

On admission the thorax was slightly deformed. Above the nipples there existed an excavation in the thoracic frame; nodosities slightly pronounced on the costal epiphyses. Auscultation of the heart and lungs revealed nothing abnormal. The abdomen was normal. The head was large; the cranium squarely built, the parietal protuberances prominent. The teeth presented no signs of rhachitis. Both humeri were larger than normal. Over the left olecranon was seen an old cicatrix caused by the operation for the cold abscess. The submaxillary glands, and those of the left armpit were increased in size. Nothing was noted as to the skin; the subcutaneous tissue was well-developed, as also the muscles; the mucous membranes were of a healthy red. A cicatrix of a former spina ventosa existed on the fourth finger of the right hand. The urine was of a pale-yellow color, and transparent; it was not rendered turbid by boiling; mixed with a solution of acetic acid, the gases produced by the formation of the carbonates were seen to escape, but no turbidity was produced. No albumin or sugar was present; the reaction was acid, the density 1010. Both legs were found to be greatly deviated, as is shown in Fig. 1. There was a very decided forward curve of both legs, and the right thigh was conspicuous. The curve of the thigh took in about equally the entire femur, while the curve in the legs was localized in a most evident manner in the lower third of both tibia and fibula. The curve was slightly more pronounced on the right than on the left side. There also existed, but very much less

FIG. 1.

pronounced, an external curve in the legs, producing a genu valgum. Neither the tibio-tarsal nor the tibio-femoral epiphyses presented any pathologic condition, excepting that the circumference of the condyles of both femora were projecting and sharply defined. The different articulations were normal, and the active and passive motions were preserved. The child walked with great difficulty, was obliged to support herself on crutches, was quickly fatigued, and without crutches she could only walk a few steps.

The operation, performed November 18, 1890, consisted in an osteotomy of the tibia and fibula of both legs in their lower third, and an osteotomy of the right femur. Dr. Kummer proceeded in the following manner: An external incision was made over the lower third of the fibula, and then the finger was introduced between the extensor digitorum communis longus muscle and the peroneus brevis muscle, thus separating them, after which they were held apart by an assistant. The periosteum of the fibula was then divided and peeled off the bone, and was pushed aside by an elevatorium placed on both sides of the fibula. The transverse division of the bone was accomplished by hammer and scissors. The hemorrhage was very slight; the incision was closed by suture; silk being employed for closing this incision, and for all the others as well. The wound was then dressed with iodoform-gauze, over which was placed a thick layer of gauze sterilized by steam under pressure. I would here remark that this is the customary dressing employed by Dr. Kummer in the greater part of his operations when infection is not to be feared. At the

[1] Surgical Clinic of the Butini Hospital, Geneva, Switzerland. Service of Dr. Kummer.

same level, an incision was then made over the crest of the tibia; the skin, subcutaneous tissue, aponeurosis, and periosteum were divided. They were then held apart, and a cuneiform excision, with the base situated anteriorly, was made in the tibia. The angle opposite the base corresponded to the angle of flexion of the leg; consequently, after this cuneiform excision, the straightening of the leg was attended with no difficulties. The incision was closed as already described. The same operation was then performed on the other leg, and here also the straightening was very easily accomplished after the cuneiform excision had been made in the lower third of the tibia. Above the articulation of the right knee a linear osteotomy was then performed on the femur. It was executed after Macewen's method, the only modification being that the line of section was not transverse, but slightly oblique in the upward direction, and from the inner toward the outer side of the bone. The straightening of the thigh was very easy after this operation. The hemorrhage was slight. A plaster-of-Paris dressing was then applied, completely covering the lower extremities from the toes to the pelvis inclusive.

The sequel of the operation was perfectly simple. Once only, five days after the operation, the temperature rose to 38° C., but declined after an enema. The plaster-of-Paris dressing was allowed to remain until December 28th (forty days), when it was removed, and perfect consolidation of the straightened bones was found to have taken place. Massage, baths and electricity were now commenced. The patient left the hospital perfectly cured on February 13, 1891, walking without crutches or a cane. She only had a slight deviation of the left leg in the sense of a genu valgum.

We saw the child in February, 1892—that is to say, one year after leaving the hospital. Her mother tells us that the child has been doing well since the operation, and continues to walk without aid. She has been regularly

FIG. 2.

at school, a thing that was impossible before the operation. The parents and the patient declare that they are thoroughly satisfied with the result of the operation. However, the child becomes tired a little more quickly than the average one of her age, and on examination we find that the left-sided genu valgum has slightly increased since leaving the hospital, while on the right side there also exists some genu valgum, although in a much less degree. On the other hand, the forward deviation of the legs, which was so pronounced before the operation, has absolutelely disappeared. (See Figs. 2 and 3.) The

FIG. 3.

general health of the child has also improved considerably, this fact being easily explained by the exercise that the child has in the open air.

I have put this case on record, thinking that it might be interesting as an osteotomy on five bones, performed in one séance, and cured at the end of six weeks by a single plaster-of-Paris dressing, without pain or fever, and with a good result, which is to all appearances a definitive one and is not common.

My thanks are due to my friend Dr. Vallette, who had the kindness to take the second and third photographs.

NEW INSTRUMENT.

A NEW TONGUE-DEPRESSOR AND AN EAR-SCREW FOR THE REMOVAL OF FOREIGN BODIES.

BY LOUIS J. LAUTENBACH, M.D., PH.D.,
OF PHILADELPHIA;
SURGEON TO THE PENNSYLVANIA EYE AND EAR INFIRMARY; CHIEF OF THE EYE CLINIC OF THE GERMAN HOSPITAL; THROAT AND NOSE PHYSICIAN TO THE ODD-FELLOWS' HOME, ETC.

I. A NEW TONGUE DEPRESSOR.

CONSIDERING the unsatisfactory character of the many tongue-depressors in use, and the necessity for one that would combine all requirements and at the same time be cleanly, I devised such an instrument in 1875, the illustration of which is here given. It consists of a solid, smooth piece of German silver, 21.5 cm. long, 3 cm. wide, and 1.5 mm. thick. The handle is 11 cm. and the tongue-support 3.5 cm. long, the two being connected by a band 7 mm. wide and 7 cm. in length. At the extremity of the spoon the metal is bent downward at an angle of about 135°. Usually the spoon-end is so fixed as to form an angle of 115° with the handle. This

angle can be readily varied if necessary, as the connecting band bends easily.

The advantages possessed by this instrument over others are: its simplicity, in that it has no joints; its smooth, polished surface making it impossible for dirt and septic matter to collect; its light weight; the quickness and ease with which it can be cleansed, as it can be either burned or boiled in a moment, and every part be reached; its small size; the fact that when in use it does not rest upon the teeth or lips of the patient, but gives its main support to the tongue at its extremity; the angle of the spoon—usually no other part of the spoon exerting any pressure—and it can be used in cases wherein almost any other instrument occasions either a tendency to retching or involuntary closing of the jaws.

Fig. 1.

A new tongue-depressor.

For rapid and careful work I have, as yet, not seen an instrument that pleases me so well. The only objection to it is the space it occupies in one's satchel. This is, however, obviated by straightening the instrument before packing and bending into shape again before using it. I have never seen a jointed tongue-depressor that could be called clean. Many depressors are made with fenestræ, which are often a disadvantage in that they allow part of the tongue to protrude, and at the same time serve as receptacles for the collection of various impurities.

Rubber depressors become discolored, and consequently look unclean, and to look so is often as great an objection as to be unclean. The metal depressor of Cohen, unjointed and made of a single piece of metal, I consider a most valuable instrument, but I find by practical experience that the bending of the tip of the tongue-end and the narrowing of all that part of the instrument between the handle and tongue in my depressor, as well as the spoon-angle, are very important items. Again, being made of German silver, it is better than either a nickel-plate, steel, or brass instrument, the nickel flaking off in the first; and it is better than silver in that it is more firm and rigid than an equal weight of that metal, while it is not acted upon by chemicals so readily. At the same time—not a minor consideration—the cost is decidedly less.

The instrument has, so far as I know, been used in this country to but a limited extent. In Europe, and especially in Geneva, Vienna, and Milan it is more generally in use, having been brought to the attention of the profession there by my brother, the late Dr. B. Frank Lautenbach, while Assistant Professor of Physiology under Professor M. Schiff, at the University of Geneva, Switzerland.

2. A NEW INSTRUMENT FOR THE REMOVAL OF FOREIGN BODIES FROM THE EAR.

In the course of treatment of an old case of necrosis of the middle ear, with two sinuses leading back of the auricle, there was, as a resultant of the long-continued inflammation and consequent acrid discharge, a very marked constriction of the external meatus. Within this constriction could be discerned polypi and masses of granulation-tissue. Upon removing as much as possible of these growths the diameter of the meatus was increased, but not sufficiently to thoroughly explore the middle ear, or enough to allow of the removal of all the overgrowth of fibro-mucous tissue. In order to make a more thorough exploration of the middle ear I resorted to the use of laminaria tents, and, later, of elm tents, to temporarily enlarge the meatus. On one occasion, when I was about to remove an elm tent with the angular forceps, the patient gave his head a sudden twist and the tent disappeared in the middle-ear cavity (the membrana tympani and the chain of bones, of course, being absent), and despite the use of tents in the meatus, sufficient space for its removal could not be obtained.

After the trial of various expedients, including the galvano-cautery, with the view of destroying the tent, or as much of it as possible, I at last devised (May 29, 1893) an ear-screw, of which the actual size is represented in the illustration. It will be observed that the screw is a double-headed one, that is, a two-threaded screw; the pitch is considerable, and the threads present an angle forward; the posterior surface of each thread is at right angles to the shaft. The screw and shaft are of hardened steel, the handle round and of ivory, allowing of easy revolution.

Fig. 2.

A new instrument for the removal of foreign bodies from the ear.

The slightest twist of the screw sends its two points into any substance ordinarily soft, such as wood or any vegetable structure. On account of its high pitch the screw travels rapidly inward. After it has made its way into any substance it will not slip out, but will, when traction is exerted, either bring with it whatever is attached to it, or tear out as much as the diameter of its threads, in consequence of the posterior surface of the thread being at right angles to its shaft.

Upon using this instrument I was at first successful in

tearing out only pieces of the tent, but after a sitting or two had the satisfaction of finding my screw firmly fixed in the swollen tent, and by gentle and persistent traction with a swinging motion, and enlarging of the meatus by an incision, succeeded in accomplishing its removal.

The instrument having been devised, it is surprising how often it proves of use. By means of it I have since removed two beans and a shoe-button from the middle-ear cavity and a piece of wood and a shoe-button from the nasal chambers.

For the removal of non-metallic foreign bodies from the middle ear I think it the most convenient and safest—in fact, with the exception of the forceps and syringe, the only instrument to be used. Before it is to be used the syringe will probably be employed, and this failing, then the screw may be tried. The forceps, on account of the room it takes in an already crowded space, is to be employed but rarely, often complicating the case by forcing the foreign body into a more inaccessible position than the original one.

For foreign bodies in the meatus, the syringe failing, the screw is to be used when the nature of the foreign substance admits of it: the forceps, in cases to which the screw is not adapted, and to a few cases in which we can be sure of its removal without incurring any danger to the membrane or the middle ear.

Both instruments have been very carefully made for me by Lentz & Sons, of Philadelphia, and my thanks are here given to them for the careful carrying out of my instructions.

1723 WALNUT ST.

MEDICAL PROGRESS.

A Mode of Controlling the Circulation through the Abdominal Aorta.—MACEWEN (*Annals of Surgery*, vol. xix, No. 1, p. 1) details a method of controlling the circulation through the abdominal aorta that he has employed for more than fifteen years and found simple, always ready, easily applied, and efficient. The subject lying on his back, the assistant stands on the left, facing the patient's feet and in a line with the umbilicus. He then places his closed right hand upon the patient's abdomen, a little to the left of the middle line, the knuckles of the index finger just touching the upper border of the umbilicus, so that the whole shut hand will embrace about three inches of the distal extremity of the aorta above its bifurcation. The assistant then stands upon his left foot, over which his right foot is crossed, resting upon the toes, and leans upon his right hand, thereby exercising the necessary amount of pressure. With the index finger of the assistant's left hand the weight necessary for the purpose can easily be estimated by the effect produced upon the flow of blood through the common femoral at the brim of the pelvis. Whenever the flow of blood through the femorals is absolutely arrested the abdominal aorta is sufficiently controlled and no further weight ought to be applied. The pressure exercised can be varied at will by increasing or decreasing the angle that the assistant's body makes with the floor. As the abdominal aorta sometimes bifurcates higher than usual, a trial of the effect of the pressure at the part selected ought to be made before the operation is commenced, testing the result of pressure upon both femorals. When both are equally controlled the bifurcation occurs below the point pressed upon; when only one is controlled the hand requires to be placed on a more proximal part. As there is no direct muscular effort required in maintaining the pressure, further than the preservation of the equilibrium, the position can be maintained by the assistant without undue strain on his part, and without shifting his hand for at least half an hour, a time amply sufficient for the performance of most operations requiring the control of the circulation through the abdominal aorta. Among the conditions in the course of which this procedure has been employed are disarticulations at the hip-joint, amputations at the upper third of the femur, large pelvic vascular tumors, intra-pelvic hemorrhage, and traumatic hemorrhage from the external iliacs; in all, the control of the circulation was absolute. In the amputations of the hip none of the patients lost from the proximal side of the cut vessels more than a couple of ounces of blood, and that only from the oozing of the general surface; there was no loss from the main vessels. In amputations, also, after the main vessels were ligated the assistant could, by a slight momentary relaxation of the pressure, "show" the position of any hidden or retracted vessel without altering the position of the hand relatively to the aorta. This form of pressure would be equally valuable for uterine hemorrhage. The pressure is, as a rule, followed by no discomfort. Should violent vomiting or coughing occur in the course of the compression the pressure would have to be increased, as otherwise the abdominal muscles might during the strain elevate the hand from the aorta. In case of vomiting, the operation might be interrupted for a few minutes while local pressure is applied.

Basal Drainage for Chronic Hydrocephalus. — PARKIN (*Lancet*, No. 3664, p. 1244) has reported a case of chronic hydrocephalus in a child, eleven months old, in which relief of threatening symptoms was afforded by drainage of cerebro-spinal fluid. The infant had a large head, the greatest circumference of which was seventeen and a half inches. The temporal fossæ were obliterated; the anterior fontanel was large and the membrane covering it was tense. There was marked separation of the two halves of the frontal bone, and to a less degree of the parietal bones. The eyes were prominent and the sclerotics were visible above the pupils. The child was fairly intelligent for its age and had had no convulsion, although it was always restless and irritable. Sight and hearing were good. There was a history of tuberculosis in the families of both parents. The enlargement of the head had been noticed from the age of five months, and had been gradually progressive. There was no history of syphilis. The child was treated with mercury and chalk, and later with potassic iodid and ferric iodid. In the course of three months the circumference of the head had increased to eighteen and a half inches, and the general condition of the child was worse; it took little or no notice of anything and frequently vomited; it lay perfectly quiet in bed, not moving its limbs or uttering the least cry, even when taken up roughly and shaken

violently from side to side. The eyes were open and staring and the head was retracted. Food was taken badly and vomiting occurred thrice in twenty-four hours. The pulse was 84. The anterior fontanel was hard and no pulsation was felt through it. A little chloroform was given and the under surface of the cerebellum was exposed about one inch below the superior curved line of the occipital bone and half an inch to the right of the middle line. The bone was easily gouged away, exposing the tense dura mater. After incision of the latter a few drops of fluid came away, but the passage of the probe into the sub-arachnoid space, with gentle raising of the cerebellum, allowed the escape of clear cerebro-spinal fluid. A horsehair drain was inserted into the sub-arachnoid space and was brought out at the inner end of the wound, which was closed with a continuous suture. On the following day the condition of the child was most satisfactory. The eyes were opened intelligently and no part of the sclerotics was visible above the pupils. The anterior fontanel was soft and pulsatile. The child moved its limbs about and recognized its mother. The wound healed by primary union. The drainage, though never very abundant, was sufficient to keep the intra-cranial tension low, as indicated by the softness of the anterior fontanel. The horsehair drain was removed eighteen days after the operation, no fluid having come away for three days. The improvement was continuous and persistent, and after the lapse of three months there was no indication of recurrence.

The Radical Cure of Hernia.—In a discussion upon the radical cure of hernia, held at the recent meeting of the British Medical Association, PARKER (*British Medical Journal*, No. 1715, p. 1037) took the ground that the radical cure of inguinal hernia in childhood and infancy can be attained with ease, almost as a matter of certainty, and that operation should be urged when the disease exists at this time of life. The cure of inguinal and femoral herniæ in men and women is considered attainable in the large majority of cases, the exceptions being sometimes the large herniæ, at other times the small. Macewen's operation is held to be the best for inguinal and femoral herniæ at all periods of life. Umbilical hernia in adults is thought to be capable of radical cure, in a proportion, however, much below that of success in femoral and inguinal, and far short of the requirements of many of the cases. The radical cure is further believed, as a rule, to be applicable to strangulated and unstrangulated herniæ alike.

THERAPEUTIC NOTES.

Magnesium Sulfate Hypodermatically as a Purgative.—From advance sheets of the Ninety-sixth Annual Report of the Maryland Hospital for the Insane we learn that, upon the suggestion of the superintendent, Dr. Rohé, one of the assistant physicians, DR. J. PERCY WADE, has made a study of the purgative action of magnesium sulfate injected subcutaneously. For this purpose forty-six patients were selected, who suffered from habitual constipation and required from two to three ounces of a saturated solution of magnesium sulfate to induce one or more free movements of the bowels. With a hypodermatic syringe, having a capacity of two drams, and properly sterilized, sufficient of a two per cent. solution of the salt was injected to represent from 1.86 to 4.5 grains. It was found that small doses acted as efficiently as large doses, and that one small dose followed in a short time by a second small dose proved more effective than a single large dose. The injections were made on the outer aspect of the left arm, midway between the elbow and the shoulder, and caused no unpleasant local or constitutional sequelæ. One hundred injections were made in all, successfully sixty-seven times and unsuccessfully thirty-three. Fifty-three times a single evacuation of the bowels was induced; ten times, two movements. In two cases of melancholia with habitual constipation that resisted nearly all purgatives the injections were absolutely futile. The shortest interval that elapsed between the giving of the injection and the evacuation of the bowels was three hours, the longest fourteen hours, the average seven. The subcutaneous injection of magnesium sulfate to induce purgation would seem indicated in case of gastritis, when a purgative is required and the stomach rebels; in abdominal surgery, when the administration of a purgative by the mouth would be likely to cause vomiting; and in cases in which consciousness has been lost and swallowing is not possible.

To Render Cocain-anesthesia safe, GAUTIER (*Gaz. des Hôp.; Wiener med. Presse*, No. 47) recommends the conjoined employment of trinitrin. Of the following solution, 15 minims may be injected subcutaneously:

℞.—Cocainæ hydrochloratis . . gr. iij.
Liquor nitroglycerin. (1 per ct.) . gtt. x.
Aquæ destillat. . . . . f℥ijss.—M.

THOMAS (*Rev. de Laryng.*) has employed the following formula by topical application to the pharynx and larynx for the production of local anesthesia:

℞.—Cocainæ hydrochlorat. . . gr. xlviij.
Liquor nitroglycerin. (1 per ct.) . ℥ijss.
Aquæ destillat. . . . . f℥j.—M.

The feeling of dryness that ordinarily follows topical applications of cocain is said not to follow upon the use of this solution, while the anesthetic and vaso-constringent action seems not to be diminished.

A Carbonated Laxative.—

℞.—Sodii phosphat. . . . ℥j.
Aquæ destil. . . . . f℥x.
Syrup. simplicis . . . f℥ij.
Tinct. limonis . . . . gtt. xxv.
Acid. citric. } . . āā ℥ss.—M.
Sodii bicarbonat. }

S.—Two tablespoonfuls, or more, as required.

PAUL, *Les Nouv. Rem.*, No. 23.

For Pruritus.—

℞.—Acid. carbolic. . . . . ℥j–℥ij.
Liq. potassæ . . . . . f℥j.
Olei lini . . . . . ad f℥j.—M.
Ft. linimentum.
S.—Apply with a soft cloth.

Practitioner, No. 306.

SATURDAY, JANUARY 27, 1894.

THE INFECTIOUSNESS OF PULMONARY TUBERCULOSIS.

IT is best, perhaps, to speak of the infectiousness of tuberculosis, and for the present to leave the question of contagion aside. The terms "infection" and "contagion" are, indeed, interchangeable; but the first expresses a remote, the latter an immediate contingency. Besides, the first is the most usual way in which the disease is transmitted. It is true there are instances of its direct transmission by contact, but then these are, for the most part, affections of exterior parts, of the joints, skin, eyes, etc. With such cases we are not in this paper particularly concerned, yet they should be remembered as showing tuberculosis in an important and significant light.

Of the infectiousness of tuberculosis of the lungs, a disease, as DR. CORNET well observes, that maintains no strongly-marked definite type, but shows variations within wide limits, there is now no longer any reasonable doubt. It is perhaps true that pulmonary tuberculosis is not so intensely infectious as is smallpox, or diphtheria, or scarlet fever. We might say, with a not too violent perversion of a classic metaphor, that it is *parasitically* infectious—that is, it flourishes most in the company of other diseases (and under these conditions really assumes the severity of an infectious disease), and on a soil specially prepared for it. It is at this point that hereditary predisposition becomes so mysteriously and characteristically important. And as to the first part of our proposition, namely, that tuberculosis of the lungs requires the alliance of other diseases, or, to speak more accurately, other morbific germs, to make its contagion effective, we must cite a profound and suggestive paper by DR. CORNET, which he entitles "Mischinfektion," wherein he shows that the numerous family of the saprophytes are the active allies of the tubercle-bacillus and that their ravages lead to those rapidly fatal cases of pulmonary tuberculosis, to the formation of cavities, etc. Another excellent authority, DR. BENNET, while he admits the infectiousness of tuberculosis, denies that it is infectious, except in "pre-breathed" air—a useful phrase, of much descriptive truth, which may be left to explain itself.

At this point we cannot do better than examine critically some of the typical cases of infection. A and B live together—man and wife. A becomes tuberculous; B nurses him. Several months pass by and A dies. Proximately B too dies of tuberculosis. In this case the presumption of infection or contagion is justly held to be very strong, and although there is here no *direct* proof of the transmission of tuberculosis, yet we are justified in believing that the disease has really been communicated by A to B, for B's conditions, as we shall endeavor to show, were just those under which this kind of contagion becomes effective. An even better instance is the following, to be found in the appendix of MR. G. A. HERON'S book on the *Communicability of Consumption*. "OGSTEN records the case of a healthy family of ten persons without hereditary taint. A son contracted consumption abroad and returned home to be nursed. His two sisters nursed him, while a brother shared his room and bed. These three and the patient all died of consumption. The parents and the four surviving sons remained healthy."[1] We look upon this case as particularly strong in favor of the infection-theory. It is scarcely possible not to believe that the brother and sisters were helped to their malady, if not actually infected, by the patient. Here, as in all other examples, there are these characteristics to be noted: First, that the infection exists amid conditions that augment its virulence. Thus we see that

[1] British Medical Journal, 1884, vol. ii.

an atmosphere which contains the bacillus and the saprophytes together—an atmosphere, as DR. BENNET excellently terms it, of *pre-breathed* air, pre-breathed by tuberculous persons, of course—is the one that carries with it the most effective contagion. Secondly, there is commonly some very close relation between the carrier and the recipient of the poison, between the person that infects and the one that is infected—a relation like that of husband and wife, patient and nurse—of such a kind that the healthy person is kept in constant attendance on the other, so that there must be frequent imbibitions of the poison, continual inoculations, so to speak, which at last have their effect. In sober truth, it is this constancy and closeness of relation, this uniformity in the condition, this unvarying danger, that forms a set of conditions from which it is difficult to escape with impunity.

That such are the conditions in which the tuberculous infection is paramount may be sufficiently seen from the first typical case that we quoted. It is profoundly significant, too, that pulmonary tuberculosis is more often communicated by the husband to the wife than by the wife to the husband. In Mr. HERON'S appendix we find fifteen of such cases described, and in thirteen the infection came from the husband, and in two from the wife. The reason must be that the wife, having, as a rule, no occupation abroad, is more constantly in the sick-room, in the midst of the infection, let us say, whereas the husband has his business and his avocations to call him away. In support of these views, we may be pardoned if we cite another typical instance of infection, an instance hardly susceptible of two explanations, as most cases unfortunately are: "A healthy young military officer, without hereditary taint, whose wife was in the last stage of consumption, took with her a sea-voyage lasting four months. On account of bad weather they were confined very much to their cabin, which was small and badly ventilated. On their arrival in London the wife died, and the husband showed the first signs of consumption." It is scarcely possible to find any better instance to illustrate the conditions of a true case of infection.

One notion of an infectious disease is that of a contagion which spreads rapidly at a rate above the mean, and never changes its epidemic form. By an endemic disease we understand one that always resides in the community. In this sense pulmonary tuberculosis is undoubtedly an endemic disease. But it never, or seldom, spreads at a rate above the mean. M. ARTHAUD,[1] indeed, has described four instances in which it has apparently assumed the severity and gravity of virulent contagion. His best example is to the following purpose: "A merchant of Paris asked me to attend his phthisical son. On inquiry I found that this lad, aged seven years, was in the habit of playing in his father's counting-house, where there was a tuberculous employé who expectorated profusely on the floor. After the son I subsequently attended the father, and then the grandfather. Of this family the mother alone, who never appeared at the counting-house, remained healthy." There was, we doubt not, a close connection between the cases M. ARTHAUD observed, a connection which points to a real danger, and which assuredly demonstrates that regular measures of prophylaxis should be enforced in any community or domicile which becomes evidently the seat of contagion. In addition to such evidence, the frequency of pulmonary tuberculosis among the Catholic Nursing Orders of Prussia has always been regarded as an instance of true infection, and one worthy of the gravest attention. For the convent-life of the nurses, its uniformity, its isolation, together with the fact that none is admitted but the robust, and that sixty-three per cent. die of pulmonary tuberculosis, form a set of conditions that, as we have endeavored to show, we hope not fancifully but on good evidence, change this disease when it exists—it might be only in a latent condition—into an infectious form.

There are, however, cases in which the foregoing conditions are not evident, and only the possibility of acquiring the disease apparently remains. Such a case is the following: A, in whom no hereditary taint was discovered, died at the age of fifty-eight, of tuberculosis of the lungs, after an illness of four years. His father, mother, and only sister died (but not of tuberculosis), aged respectively eighty-seven, seventy-one, and seventy-seven years. RIFFEL[2], who quotes this case, had unexampled opportunities to study A's antecedents back through two hundred years. He asserts that he could not have been infected at home, or in any intercourse without, for the patient in question led a perfectly uniform

[1] Annales de la Policlinic de Paris, 1892, p. 49.

[2] Mittheilungen über die Erblichkeit und Infektiosität der Schwindsucht, Braunschweig, 1892, p. 166.

life in his native village, and never stirred from thence. In what sense, then, can this be called a case of infection, or is there any infection here? MR. HERON, a radical thinker on this subject, attributes such cases to some hereditary tendency toward tuberculous disease. He cites a case,[1] of a family of eight persons, of which seven died of pulmonary tuberculosis, but these seven people were so far removed from each other that there could not possibly have been any connection between these cases, as there would have been if infection were the cause.

It will thus be seen that our conceptions of the infectiousness or the contagiousness of a given disease will depend upon our interpretation of these words, and upon this subject we may have more to say at another time.

THE OPERATIVE TREATMENT OF AKROMEGALY.

ALTHOUGH our knowledge of the symptom-complex first described by MARIE, and by him given the descriptive name of akromegaly, is of comparatively recent date, the clinical picture has become a perfectly well defined and familiar one. Our knowledge of the pathology of the affection, however, is much less certain. The only lesion that has been found to which a causative influence could be attributed is hyperplasia, or other enlargement, of the apophysis cerebri, the pituitary body; but this lesion has been by no means constant. In some cases changes in the thyroid gland have been present, sometimes hyperplasia, sometimes atrophy. The more characteristic anatomic changes consist in a hyperplasia of the tissues that originate from the mesoblast, *i. e.*, those of the connective-tissue group: bone, cartilage, areolar tissue. Therapeutically little or nothing has thus far been accomplished. In the absence of a definite pathology the treatment has been symptomatic and empiric. In a few cases, upon the basis of a functional relationship between the thyroid gland and the pituitary body, extract of thyroid gland has been administered, but without encouraging results.

In the face of this hopelessness of the prognosis, and in view of the boldness and, we may add, the precision of modern cerebral surgery, respectful consideration should be given to any proposition calculated to bring relief by operative interference in cases in which it can be definitely determined that the pituitary body is enlarged, and that threatening symptoms arise as the result of the compression of adjacent structures to which this enlargement gives rise. Such a procedure has actually been undertaken in a case reported in a recent number of the *British Medical Journal* (No. 1722, p. 1421) by DR. RICHARD CATON, Honorary Physician to the Liverpool Royal Infirmary, unfortunately, however, with a fatal outcome, although the patient lived for three months after the operation, and was relieved of the intense pain from which she had previously suffered. The case was, briefly, that of a married woman, thirty-three years old, who presented the classic train of symptoms of akromegaly. Those peculiar to the case consisted of pain in the distribution of the left facial nerve and some loss of sensibility over the left half of the lower jaw; degenerative changes took place in the optic papillæ, with loss of sight, and hearing was also lost; late in the history of the case albumin appeared in the urine from time to time. When it became evident that there existed intra-cranial pressure, operative interference was proposed, but was not acquiesced in by the friends of the patient. At a later date, however, the necessary consent was obtained. The opinion of MR. VICTOR HORSLEY was secured, who agreed to the propriety of operation, which was undertaken by MR. F. T. PAUL, Honorary Surgeon to the Infirmary.

Although the removal of the tumor at this time was not considered feasible, it was hoped that by making an opening in the skull and relieving the intra cranial pressure, the intense pain could be relieved, and that by making this opening in a suitable position it could, if desired, be subsequently enlarged and the removal of the pituitary body undertaken. As the right eye was useless, it was decided that the bones forming the anterior portion of the right temporal fossa should be removed at the first operation, and if at that time or subsequently any attempt were made to remove the tumor, the right orbit should be emptied and the aperture in the skull enlarged by the removal of its outer wall. The dura at once bulged into the opening as soon as three or four square inches of its surface had been exposed; and no pulsation of the brain could be discerned. Some vessels in the dura oozed pretty freely, and as this bleeding was unaffected by irrigation with hot water a soft, new, sterilized sponge was laid in the wound and covered by the flap, and the site of operation dressed with iodoform, cyanid-gauze, and salicylated wool. The

[1] Evidences of the Communicability of Consumption, p. 112.

sponge was removed on the following day and the flap placed in position. The wound never closed entirely, but, as already stated, the patient was relieved of her previous intense suffering, and lived for three months. At no time was her condition considered suitable for the more severe operation.

Upon post-mortem examination the pituitary body was found to be as large as a Tangerine orange, projecting half an inch above the level of the lesser wings of the sphenoid bone. Microscopic examination demonstrated the existence of a new growth, presenting the histologic structure of a round-celled sarcoma. The optic chiasm and the adjacent portions of the optic nerves were flatted, but not involved in the growth. The sella Turcica measured one and one-half inches antero-posteriorly, one and one-third inches transversely, and one-half inch in height. Of course, the unfortunate outcome of the case is to be regretted, but this lay in the nature of the case itself rather than in a failure of the operation or of the principles on which it was based. Whether or not more could have been accomplished had the operation been consented to and undertaken earlier must remain a matter of doubt. At any rate the lesson is an instructive one; and in future the propriety of operation in selected cases of akromegaly should receive due consideration.

EDITORIAL COMMENTS.

The State Board of Medical Examiners.—It is announced that Governor Pattison has selected from the membership list of the State Medical Society the following gentlemen as members of the Pennsylvania State Board of Medical Examiners, representing the regular medical profession: H. G. McCormick, of Williamsport, for three years; Henry Beates, Jr., of Philadelphia, for three years; W. J. R. Kline, of Greensburg, for three years; A. R. Hulsizer, of Philadelphia, for two years; N. S. Foster, of Pittsburg, for two years; J. E. Silliman, of Erie, for one year; and Samuel W. Latta, of Philadelphia, for one year. The President of this Board, together with the Presidents of a Board of Homeopathists and a Board of Eclectics, the Lieutenant-Governor, the Attorney General, the Secretary of Internal Affairs, and the President of the State Board of Health, constitutes a Medical Council, to which will be submitted the questions proposed to be asked applicants for license to practise medicine in the State of Pennsylvania; and from these the Council will select the questions to be asked, except in the departments of materia medica, therapeutics, and practice of medicine. The Council will meet twice a year and supervise the examinations of the State Boards, and issue to the successful applicants licenses to practise medicine and surgery. The first meeting of the Examining Boards will be held on the first Tuesday of April. Successful candidates must further register in the respective counties in which they propose to practise. Applicants who will receive their medical degrees after July, 1894, must have attended at least three courses of lectures in some legally incorporated medical college, and after July, 1895, attendance upon at least four courses of lectures will be required. An applicant who fails in the first examination may again be examined after the lapse of a period of not less than six months or more than two years. Physicians licensed in other States, in which the standard of requirements is substantially the same as in Pennsylvania, will be entitled to a license without further examination. The new legislation does not affect physicians already regularly registered; nor does it apply to physicians from other States called in consultation with registered physicians in this State. Pitiful as must be the tacit admission by those who may not have thought seriously upon the subject, that there can be more than one kind of medicine and one kind of physician, it is still a source of congratulation that at least the worst forms of incompetence and downright quackery will no longer find the soil of Pennsylvania adapted for their propagation. At the same time an irresistible impulse has been given to the movement for higher medical education, inasmuch as all medical colleges that hope to have their pupils receive recognition in the Commonwealth must maintain a definite standard, and lengthen their course of study to at least four years.

A Legal Dispensary.—The novelty of a legal dispensary based upon the same general principle as the medical dispensary, has been organized by the students of the Law School of the University of Pennsylvania. As far as can be learned the institution is the first of its kind established in this country in connection with a law school. For the present, services are to be held twice a week in the evening, and will be available to all persons that have been wronged and seek redress by legal means, but are unable from poverty to retain a lawyer in the ordinary way. No charge is made for services, but if a case is taken into court the client must pay the actual costs for papers, minor services, and the like. It is said that the idea of the dispensary was suggested by a reflection cast upon the legal profession in an address upon medical ethics by Dr. Weir Mitchell by the inquiry "Who ever heard of a law hospital?" In a lecture delivered in Philadelphia some two years ago by Dr. Gould, among other things, it was said: "Every hospital of the land is carried on by the unpaid labor of physicians. Is there *one* great institution, or one ever so little institution, where poor folks can go and get legal advice, counsel, and help gratis?" Properly conducted, the new dispensary should prove doubly beneficial and must be considered a distinct ethical advance.

Microphotograph and Photomicrograph.—There is a lack of clearness as to the definitions and in the use of these two terms. Etymologically the term *microphotograph* should mean *a small photograph*. There is nothing in the formation of the word implying that the object photographed is either small or large, but in most cases the object is of microscopic size. It is manifestly absurd, as has been done, to force the word to stand for "an enlarged photograph of a microscopic object," as the

prefix *micro-* forbids that. On the other hand, the word *photomicrograph* etymologically authorizes the definition, *a photograph of a small or microscopic object.* Here again there is nothing in the formation of the word implying anything as to the size of the photograph, though it is also usual that the photograph is made with a microscope, and of sufficient size for observation with the naked eye. In German and French usage the term microphotograph is almost the only one used—evidently a loose custom, that does not permit of making an important distinction in the facts. English and American scholars have long recognized the necessity of both distinctions, which is summed up by Dr. Mercer in this way: "A photomicrograph is a macroscopic photograph of a microscopic object; a microphotograph is a microscopic photograph of a macroscopic object."

A National Bureau of Health.—If present indications lead aright the long-deferred organization of a National Bureau of Health will soon be a reality. The people seem to have awakened to the necessities of the case, and prompt action may be expected. The proposed measure has received the indorsement of nearly every medical society in the country and has encountered no real antagonism, and large numbers of petitions have been presented in its favor. The only fear is that the legislation may be pushed aside by other less important matters. It is to be hoped, however, that the agitation will be kept up until the bill that is now before both houses of Congress has been finally passed. It is believed that the President, the Secretary of the Treasury, and administration officials generally are favorably disposed toward the bill. The President, in his annual message to Congress, strongly recommended additional safeguards for the public health such as are proposed by this measure.

SELECTIONS.

HOSPITALS AND THE PROFESSION.

I UNDERSTAND that some two millions of people in London receive medicine and medical attendance gratuitously per annum, and I do not doubt that the proportion is not less in this city. It is a favorite argument that the number of practitioners has not much increased during the past thirty years, while the population has enormously increased, and thus encouragement is given to the young physician. But for one person treated gratuitously thirty years ago, there must be now ten who receive medicine and medical attendance on this condition. I state it with some humiliation, and as showing somewhat the reverse side of the beatific picture, that any number of highly educated practitioners are willing to take and compete for medical-club appointments for the paltry sum of two shillings six pence per annum for medicine (so-called) and medical attendance. Eliminate the class of people quite able to pay this paltry sum for this boon, and it surely must diminish the number entitled to free medical attendance and medicine apart from the State. I go further, and maintain that the individual who cannot lay aside from his earnings two shillings six pence per annum for such a contingency as medical attendance and medicine is *ipso facto* a pauper, and ought not to be ashamed to be treated as such. Any man in receipt of anything over from twenty to twenty-five shillings per week, who receives medical treatment gratuitously, is thereby demoralized, and the profession is being robbed by any agency, call it what you like, that panders to him in this direction. Surely an income of even ten shillings per week can afford two shillings six pence per annum for medical attendance. Never having held a club appointment, I am free to confess that I see nothing wrong in the club system; it is the principle on which life and other assurance is based, and it is infinitely better to combine for anything than to accept gratuitously that which ought to be honorably paid for. It is at this point that the hospital and the younger and poorer practitioners come in conflict, and the hospital being the stronger, the practitioner comes off second best in the struggle.

Who, then, is to blame for the penny, the threepenny, and the sixpenny dispensary system so rampant in London, and which I certainly regard as an undoubted professional humiliation? But if the value of medical services is estimated by what is paid for them, is threepenny advice not infinitely better than that for which nothing at all is paid? The fact is this, Guy's Hospital physicians and surgeons, and the physicians and surgeons of all large hospitals, give their advice for nothing or next to nothing, and thus rob the junior, seeing that by so doing they are enabled to get enormous fees from the wealthier sections of the community. But is there any exclusive right so to do vested in any portion of the profession? Has one man not as good a right as another to treat poor people, and thus get experience and reputation, and consequently material advantage? To the former of these questions my answer is an emphatic No; to the latter an equally emphatic Yes. This, and this alone, is the *raison d'être* of the ever-increasing number of our hospitals and special institutions.—PROFESSOR D. CAMPBELL BLACK, *Inaugural Address, Anderson's College, Glasgow, Scotland.*

SANITARY REFORM.

THE labors of the true sanitary reformer lie in four directions:

1. In an endeavor to understand simply the nature of diseases, their alliances, their true distinctive characters, the modifications to which the body is subjected under the influence of diseased action, and the chemical or physical measures best adapted for the removal and prevention of disease. Labors of this kind require the highest order of medical intellect; they are altogether removed from the business of the mere politician; and they imply in him who prosecutes them a mind fully charged with all the modern doctrines of chemistry, physics, and the laws of life. These labors tend to lead the mind from effects back to causes.

2. In an endeavor to seek out primarily the causes of diseases, irrespective of the symptoms and the other details involved in the consideration of the diseases themselves. Efforts in this line of research should embrace observations conducted on a large scale, and bearing on the effects of locality, climate, season, meteorology, contagion, habit, diet, and occupation, in so far as they give rise to distinctive types of disease.

3. In striving to make accessible to all classes of society the vast stores of information already acquired in regard to the two forms of inquiry noted; and in having them scientifically popularized and diligently taught, especially amongst the child-population.

4. In giving free scope and encouragement to those mechanical arts which tend to improve the beauty and convenience of towns and cities; in lessening muscular labor; in increasing the comforts of the poor man's home; and in instituting such an elevated class of amusements and occupations for leisure moments as shall make the heart happy and the mind healthy.

In these offerings to reason and knowledge lies the one and true *elixir vitæ*, the beginning and the end of sanitary science.

Principles ignored, all else is practically mere dilettanteism, mere playing with details of principles, the principles themselves being undeveloped—a common error. Right honorable and honorable gentlemen may debate in the senate-house, may sit on committees of inquiry, publish tons weight of blue-books, and invest magistrates with new powers; but the mortality-tables of the Registrars-General will continue to tell how little can be done until a new educational impulse is given to the people, leading to personal health, to health of the whole community, springing from health in the unit of that community.—Dr. B. W. Richardson, *in The Asclepiad.*

CORRESPONDENCE.

TWO FURTHER SUGGESTIONS FOR THE RELIEF OF INGROWING TOE-NAIL.

To the Editor of The Medical News,

Sir: On page 622 of the last volume of your valuable able journal (November 25, 1893) there is published a clinical lecture of mine concerning ingrowing toe-nails, and varoius other lesions of the toes and feet. Among other methods of treating ingrowing nails which I there mentioned was one of excision of a piece from the side of the toe in such a way that cicatricial contraction would draw the redundant tissue away from the nail, pressure being thus obviated. I stated that this method was first suggested by a charlatan, and being found good had been adopted in the general practice.

A little while ago I received a letter from Dr. George W. Gay, of Boston, in which with a little good-natured chaffing he asked me to give my authority for this statement, saying also that the method had been advised and published by Dr. Cutting. Being averse to casting the slightest implication upon so worthy a practitioner as Dr. Cutting, I ask you to give me space to say, as I did personally to Dr. Gay, that the statement was quoted from one which I often heard during my instruction eighteen or twenty years ago in the Chicago Medical College, when I was under the surgical tutelage of Dr. Edmond Andrews. That statement was certainly made long before Dr. Cutting wrote his article for the *Reference Handbook*, but I am unable now to do more than make my apologies to Dr. Cutting, in case he or anyone should construe the published remarks to refer in any way to himself. I am the more glad to be able to do this because I think the method a good and sensible one, and prefer to regard it as coming from legitimate sources rather than from the brain of a charlatan.

To my surprise my remarks, as noted in your journal, brought me several other communications from gentlemen whom I esteem, concerning methods of treating this most exasperating little condition. In this way there have been suggested to me two methods which I have not personally employed or known of, but which I think are well worthy of publication. My first letter was from Dr. M. A. Veeder, of Lyons, N. Y. He says: "There is a plan that I have devised and employed for ten years past which answers very well in the ordinary run of cases of this disorder, and likewise in certain forms of onychia. It consists simply in cutting a piece of ordinary felt plaster, sold for use in cases of corns or bunions, so as to be the exact size and shape of the nail about which the ulceration is located. The bit of plaster thus shaped and fitted to the nail is to be firmly attached thereto, so as to press aside the overlapping granulations from off the nail. By holding it in this position a minute or two, until it dries and adheres firmly to the nail, it becomes strongly fastened and will stand considerable rough usage, but as an additional security I wrap a strip of isinglass plaster three or four times around the toe, including the felt. If properly applied the relief is immediate, and the cure is complete as soon as the thinned and jagged edge of the nail underlying the granulation has grown out to its normal size. I have made a note of this method in one or two medical journals, but no attention has been paid to it except on the part of those to whom it has been personally explained or demonstrated."

Another letter was recently received from Dr. Bogman of Zanesville, O., who writes regarding his own method. He says: "My maternal grandmother, both parents, and all the children, had ingrowing toe-nails from early youth. My own four children, the oldest twelve and the youngest three, all are affected. There is scrofula on all sides, but no tight or ill-fitting footwear. I was not perhaps ten years of age when my mother had both great toe-nails avulsed three times, each operation being followed by reproduction of a worse-deformed nail, and its outgrowth accompanied by extreme suffering, nearly causing tetanus. She summoned Dr. Miller, of Providence, R. I., and in my presence demanded that he operate again, but in her way, and as follows: Place the foot on a plank, crowd the flesh as far as possible toward the side proposed for operation, pressing the toe firmly down. With one stroke of a mallet drive a chisel through the nail and flesh, vertically, at the point where the nail begins to incurve and extending from the end of the toe to the joint. Repeat the same operation on the other side. Dr. Miller declined to operate thus. He was informed that she would do it herself. He knew his patient well and yielded. I cannot forget her argument in support of her theory: 'Doctor, if there is no nail to grow into the flesh, and no flesh for the nail to grow into, surely there can be no ingrowing nail.' The operation was performed on the following day. The offending portion of the nail and flesh was cut from both great toes on both sides, with the result of leaving the toes with a nail, and at this writing it is one-half inch in width and of natural curvature. Anteriorly the toes are wedge-shaped, the nails forming the wider or thicker, and the bottom of the ball the thinner end. The nails

and toes have given no further trouble, and it is now about forty years since the operation.

"I first read medicine with Dr. Miller and know that he operated several times by this method, and had chisels made, right and left, with one corner curved in such a manner as to avoid the tuberosity of the distal phalanx near the joint. He published the operation as his own, and was severely scored by Prof. S. D. Gross for his crude and unsurgical methods, which savor more of the carpenter than of the surgeon. At a later period, while a pupil of Dr. Gross, I excused the methods by explaining whence they came. As you no doubt know, Dr. Gross did essentially the same operation, using a bistoury to excise the offending portion of the nail and flesh at a single stroke. When I took the whip in my own hands I reasoned, after two such operations, that the large ulcer and cicatrix were objectionable. Avulsion of the entire nail seemed equally so, as the toe thus lacked its natural protection. I therefore and therefrom devised an operation, and first performed it in 1872. I have repeated it twenty-three times within my memory, with satisfaction to my patients and to myself except in the first case. Such nails are usually thickened or very brittle. I therefore soak the foot in warm water to soften the nail, and then place it in cold water to contract the bloodvesssels. With a strong, pointed knife I cut, not split, the nail longitudinally along the line of first indication of incurvation from before backward, and carry the incision backward to and *beyond* the matrix. With another thin knife I deepen the incision vertically to two-thirds the thickness of the toe, keeping close to the bone, but avoiding the periosteum. I then incise the flesh on the same side of the toe parallel to the incision in the nail, forming a flap of the integument and as much as may be of the cellular tissue, thus forming anteriorly a V. Grasping the portion to be excised entirely with the forceps and lifting it to near the matrix, I dissect out as thoroughly as possible its full width and depth, removing the matrix intact. Closing the wound with adhesive strips, there is present a hair-line of cicatrix along the side of the nail, but opposite the matrix is a small point which must heal by granulation. The worst-deformed case on which I operated was a patient, a druggist without a clerk, driven to immediate operation by extreme suffering, who was detained from his business but two and a half hours, and this principally by nausea from the anesthetic. Both toes were operated on, on both sides, and all dressings were removed on the eighth day without inconvenience. I gain by this form of operation the smallest possible amount of cicatrix, the preservation of an adequate portion of the nail and the entire ball of the toe, with least detention from business."

Both these methods seemed to me of sufficient value to reproduce what I have quoted for the benefit of those whom it may concern.

Very truly yours,

ROSWELL PARK.

BUFFALO, N. Y.

THE CONTAGION OF PUERPERAL FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: The profession has in the past been almost unanimously of the opinion that puerperal fever was a highly contagious disease, and a well-known London practitioner and the author of a standard work on the practice of medicine has stated that no physician should engage in midwifery practice for at least three weeks after attending upon a case of puerperal fever.

A very interesting discussion has recently taken place in the Obstetrical Society of London upon this subject. The experience of a majority of the speakers agreed with my own, that by cleanliness and the use of antiseptics a medical practitioner can engage in midwifery practice, although he has been recently in attendance upon a patient suffering from puerperal fever. By keeping the nails and hands scrupulously clean, and by washing them in an antiseptic lotion repeatedly during the time he is in attendance upon the case, I am quite satisfied that the danger of conveying the poison is very slight. To illustrate this I shall give a brief report of some cases in my practice three years ago:

In November, 1890, I was attending a patient with puerperal fever, and visited her for the last time on Sunday, 17th, on which day she died. Having been engaged to attend a number of labor cases, I had doubts as to the advisability of doing so; but after mature consideration I decided to take charge and use antiseptic measures. On the Friday following (22d) I saw the first case. The labor was tedious, but natural. On Sunday (24th) a second case came off. This was attended by profuse hemorrhage, leaving the patient exhausted. On Monday (25th) a third case was attended. These patients were visited by me daily for the usual period, and all recovered without a bad symptom. They were all young women, with fairly good constitutions. The antiseptic measures adopted were washing my hands thoroughly in a warm solution of carbolic acid every time I made vaginal examinations, and having the genitalia of the patients sponged with a carbolic solution after delivery.

It would seem, therefore, that by adopting antiseptic measures—and every medical man should do so—the risk of conveying the poison is reduced to a minimum.

Respectfully,

C. H. L. JOHNSTON, S.R.C.S., L.M. (Edin.)

ST. JOHN, N. B., CANADA.

NEPHRITIS WITHOUT ALBUMINURIA.

To the Editor of THE MEDICAL NEWS,

SIR: I would consider it a great favor if those encountering in hospital or private practice cases of suspected chronic nephritis of the sort referred to on page 671 of THE NEWS of December 9, 1893, would give me an opportunity to study such cases, as well as the urine. I am desirous of collecting and analyzing a sufficiently large number of these cases in order to arrive at some definite idea as to the frequency of their occurrence, their detailed symptomatology, and their precise pathology. The cases are not those exhibiting the ordinary symptomatology of renal fibrosis, or contracted kidney, such as are usually encountered in middle life or in the aged, but rather cases in which there is very slight or even no detectable cardiac hypertrophy or anterior sclerosis, and in which, notwithstanding the absence of albumin from the urine, the amount of the latter passed is habitually below the normal. In these there are present, besides increased arterial tension, also

headache, vertigo, nausea, and pain in the loins, all aggravated by physical exertion.

Respectfully, D. D. Stewart, M.D.

2620 N. Fifth St., Phila.

NEWS ITEMS.

Eleventh International Medical Congress.—It is announced by the Secretary-General of the Eleventh International Medical Congress that American members will pay on the English, French, and Italian railways single fares for double journeys, and will obtain a reduction of 20 per cent. on fares for Italian round-trip tickets.

The documents required for their identification will be sent to Dr. A. Jacobi, Chairman of the American National Committee, in January, and Americans intending to visit the Congress will have to apply to him for them.

Full particulars concerning the journeys will accompany the documents.

Messrs. Thomas Cook & Son, London, Paris, Rome, and Naples, should be applied to for accommodation and for tickets for the excursions to Rome, Naples, and to Sicily. Such excursions will be arranged at Rome under the guidance of Mr. Forbes, member of several scientific societies and correspondent of the *Times*, for Naples, three days, including Vesuvius, Pompeii, Capri, Sorrento, Castellamare, Bajae, etc.; for Sicily, ten days from Naples, including Messina, Taormina, Catania, Girgenti, Siracusa, Palermo, and return to Naples.

The fares for members of the Congress will be considerably reduced and comprise hotel accommodations, carriages, guides, boats, etc., about 70 francs each for the three days, and 285 francs for the ten days.

Full particulars concerning these excursions will be contained in a leaflet to be added to the instructions and documents for the journey.

The members' fee is five dollars; that of their wives or adult relations, two dollars each. Checks or money-orders may be sent to Prof. L. Pagliani, Rome, Italy. Credentials have been promised in the near future. When they arrive (none were received last year) they may be too late for many who have started or are about to start. Dr. Jacobi, who is not informed of the cause of delay, proposes to supply in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. The North German Lloyd has promised to recognize them. It is suggested, besides, that a passport may increase the traveller's facilities.

Only the North German Lloyd (22 Bowling Green) and the Compagnie Générale Transatlantique (3 Bowling Green) has thought fit to grant any reductions to Congressists.

The reductions on Italian railways are available from March 1st to April 30th.

The Faculty of the Medico Chirurgical College of Philadelphia has created three new clinical chairs, viz.: One of Genito-urinary Surgery, one of Orthopedic Surgery, and one of Otology. These, together with the vacancy in the chair of Clinical Medicine, will be filled permanently at the close of the present session.

The Fifth District Branch of the New York State Medical Association will hold its Tenth Annual Meeting in Brooklyn on Tuesday, May 22, 1894. All Fellows desiring to read papers will please notify the Secretary, E. H. Squibb, M.D., P. O. Box 760, Brooklyn.

The Canadian Medical Association will hold its next annual meeting at St. John, N. B., in the month of September of the current year. The Association has had a long and useful experience, and has done much to unite and further the interests of the Canadian medical profession.

ORIGINAL ARTICLES.

THE MORBIDITY AND MORTALITY OF NEGRO CONVICTS.[1]

BY R. M. CUNNINGHAM, M.D.,
OF ENSLEY, ALA.;
MEMBER OF SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION; OF THE ALABAMA, GEORGIA, AND TENNESSEE TRI-STATE ASSOCIATION; OF THE JEFFERSON COUNTY (ALABAMA) SOCIETY; JUNIOR COUNCILLOR OF MEDICAL ASSOCIATION OF ALABAMA; EX-PENITENTIARY PHYSICIAN, ETC.

IT is my purpose in this paper to present a few practical facts, with such deductions as may be logically made therefrom, concerning the morbidity and mortality of the negro as a convict.

Since my connection with the convict system of Alabama, there have been but two races represented in our convict population: the Caucasian and the negro—the latter including that hybrid of humanity, the mulatto of all shades. From the consecutive examination of some 2500 convicts that were in the penitentiary in March, 1883, and received from jail from that date to October, 1884, and from March, 1887, to October, 1890, it appears that 15.43 per cent. were white, and 84.57 per cent. were negroes, or in a ratio of 1 white to 5.41 negroes. Questions of health, morbidity, and mortality, then, practically mean the consideration of these important subjects in connection with and as applying to the negro race.

It appears from the penitentiary physician's and inspector's reports,[2] covering a period of nine years and seven months, that there were, from all causes, 553 deaths. Of the 553 deaths, 37, or 6.67 per cent., were among white convicts, and 516, or 93.33 per cent., among the negro convicts. Thus the ratio of white to negro deaths was 1 to 13.94, while the percentage of mortality of the white and negro was as 1 to 2.57. That is to say, that out of an equal number of white and negro convicts the mortality would be more than two and a half times greater in the negro.

Of the 553 deaths, 70, or 12.65 per cent., died from the direct and indirect effects of violence—accidental, suicidal, or homicidal. Of the 70 deaths from violence, 14 were white, or 37.83 per cent. of the total mortality among the white convicts; 56 were negroes, or 10.85 per cent. of the total mortality among the negro convicts. This leaves, dying from disease, including not known, 483, to wit: White, 23, or 4.76 per cent.; negro, 460, or 95.24 per cent; ratio of white to negro deaths from disease, 1 to 20, while the actual percentage of mortality is 1 to 3.69. That is to say, out of an equal number of white and negro convicts, the mortality of the latter would be 3.69 to 1 of the former, or a little more than 250 per cent. greater.

From these figures the following facts are established:

1. That there were nearly 5.50 times as many negroes as whites committed for crime.

2. That the negro mortality was nearly three times greater than the white.

3. That over one-third of the white deaths were due to violence.

4. That only a little over 10 per cent. of the negro deaths were due to violence.

5. That from an equal number of white and negro convicts there would be a little more than 3½ of the latter to 1 of the former that die from disease.

From these facts it may be logically concluded:

1. That (taking it for granted that our laws are impartially administered so far as race is concerned) there is something in or about the negro, some inherent principle or acquired property (the former being a part of his original creation, or from long-continued hereditary influences—the latter from environment, religious, social, or political), that prompts him to acts of crime, or that there is a deficiency of that restraining power that limits the action of the universal depravity of the races.

2. That as a physical entity he is, so far as his convict life is concerned, inferior to the white man, in anatomic formation and physiologic performance of function; or there is something in him that more greatly predisposes him to disease; or that aggravates the type of disease; or that he is wanting in recuperative or reconstructive power.

The first question I leave to the political economist, the moralist, or the philanthropist.

The second, however, to those who are responsible for his health and life, is a problem of absorbing interest. Strange to say, this aspect of the convict-

[1] Read before the Alabama State Medical Association, 1893.

[2] From March, 1883, to October, 1884, including only State convicts, wherever confined; from October, 1884, to October, 1886, State and County convicts; from October, 1886, to October, 1888, including only State and County convicts at the Pratt Mines; from October, 1888, to October, 1890, including State and County convicts at the Pratt Mines and State convicts at the walls at Wetumpka; and from October, 1890, to October, 1892, State convicts at the walls and at the Pratt Mines.

problem in Alabama has never received the attention it deserves, so far as the question of prison-life, work, and discipline affects the health and lives of negro convicts. So far as I know, there has never been any attempt to compare the mortality and morbidity of white and negro convicts, with a view of ascertaining the differences, if any exist, and the causes therefor.

I submit below in parallel columns, one for whites and one for negroes, a classification of the primary causes of death:

	NEGRO.	WHITE.
Unknown	37	1
Violence	56	14
Pulmonary tuberculosis	72	1
Peritoneal "	27	1
Acute miliary "	25	0
Miscellaneous "	40	3
Croupous pneumonia	66	2
Catarrhal "	4	0
Fibroid "	7	0
Pleurisy	11	0
Typhoid fever	26	3
Other fevers	16	0
Meningitis	15	3
Meningitis (tuberculous)	2	0
Pericarditis	3	0
Endocarditis	0	1
Organic heart-disease	28	3
Aneurism	2	0
Dropsy	5	0
Gastro-enteritis	27	2
Dysentery	1	1
Tertiary syphilis	2	0
Pernicious anemia	0	1
Erysipelas	2	0
Apoplexy	2	0
Paralysis	0	1
Lumbar abscess	1	0
Measles	1	0
Carcinoma	2	0
Bright's disease	2	0
Miscellaneous	19	0
Cystitis	1	0
Intussusception	1	0
Hip-joint disease	1	0
Pott's disease	3	0
Measles	7	0
Convulsions	2	0
	516	37

As a supplement to the foregoing, I submit also in parallel columns, one for white and one for black, a classification of the complications existing:

	NEGRO.	WHITE.
Croupous pneumonia	22	2
Catarrhal "	9	0
Pleurisy with effusion	16	0
Pulmonary tuberculosis	1	1
Tuberculous meningitis	5	0
Acute miliary tuberculosis	4	0
Tuberculosis of bowels	2	0
" of larynx	1	0
Organic heart-disease	8	1
Pericarditis	7	0
Atheroma	1	0
Tuberculous pleurisy	4	0
Gastro-enteritis	11	0
Perforation of bowels	10	1
Meningitis	5	0
Pleuro-pericarditis	1	0
Pneumonia and meningitis	1	0
Cystitis and stricture	1	0
Dropsy	7	0
Erysipelas	3	1
Dysentery	1	0

Measles	2	0
Jaundice	2	0
Bronchitis	2	0
Myocarditis	2	0
Pulmonary	4	0
Pericarditis and meningitis	1	0
	164	6

In discussing these tables, the 70 deaths from violence, and 37 "not-known" causes, are not here considered, leaving negroes, 424, and whites, 22. It appears that the primary diseases in the 424 negro deaths involved the thoracic organs in 265, or 62.50 per cent., to wit: Various forms of tuberculosis, 137; of pneumonia, 84; pleurisy, 11; heart, pericardium, and large bloodvessels, 33.

Of the 22 white deaths, the thoracic organs were involved with the primary disease in 9, or 40.90 per cent., to wit: Tuberculous disease, 4; pneumonia, 2; organic heart-disease, 3. It thus appears that there were nearly double the deaths among negroes from acute and chronic thoracic disease.

Add to these the same classes of disease in the complications, and we have 358, or 84.43 per cent., among the negroes, and 14, or 63.63 per cent., among the whites. These complications were in many cases the cause of death, but they do not represent a corresponding number of convicts, as sometimes two or more complications existed in the same case.

From acute febrile diseases there were 42 deaths, or 9.90 per cent., 26 from typhoid and 16 from other forms of fever, among the negroes; 3, or 13.63 per cent., among the whites. Occurring as a primary disease and as complications, there were among the negroes 50 cases of organic heart-disease, 36 chronic and 2 of acute myocarditis, 12 of pericarditis, making a total of 50, or 11.71 per cent.; whites, 6, or 27.22 per cent. Meningitis occurred as a primary disease and as a complication in negroes in 20 cases, or 4.71 per cent.; whites in 3 cases, or 13.63 per cent. Tuberculous disease in all forms existed as a primary disease or complication among the negroes in 182, or 42.92 per cent.; among the whites, in 6, or 27.27 per cent. Croupous pneumonia existed

among the negroes in 88, or 20.75 per cent.; among the whites, 4, or 18.18 per cent.

From the foregoing facts the following conclusions are legitimately reached:

1. That there is a much larger class of diseases represented among the negro than among the white deaths.

2. That the whites are more liable to die from accident, meningitis, and the essential fevers, than the negroes.

3. That the negroes are especially predisposed to tuberculous disease, the various forms of pneumonia, pleurisy, and organic heart-disease; in other words, to thoracic diseases generally.

The problem therefore resolves itself into the inquiry: Why are negro convicts predisposed to the development of these diseases?

1. Is it due to any deficiency in the anatomic development or formation? I shall have very little to say in answer to this question. Aside from the well-known facts—the black skin, flat nose, and flat foot, and the like—there is, in the negro race, as compared to the white, a lesser cranial and thoracic development and a greater abdominal and genital development. It is apparent to us all that the cranium is smaller in the negro than in the white; that the cranial capacity is less necessarily follows. Post-mortem examinations have convinced me that the cranial wall is thicker, the brain smaller, the convolutions less prominent, and the sulci more shallow. Hence, the inevitable conclusion follows that brain-function is not equal to that in the white race.

An examination of hundreds, or rather several thousand negroes, has convinced me that the normal thoracic movements in ordinary respiration are deficient, and that the thorax is not capable of as great movement during forced inspiration and expiration.

If this be true, what is the reason?

Does it lie in the want of muscular development, mobility of the bony walls, pulmonary elasticity or capacity, or in the encroachment of the abdominal organs below? In my judgment the causes are to be found: (*a*) in less lung-capacity; (*b*) less muscular development, particularly of the accessory muscles of respiration; and (*c*) the greater or less encroachment of the abdominal organs. The first two are largely conjectural; but I think the latter is susceptible of demonstration by physical signs. Examine, for example, a series of whites and a series of negroes, noting carefully the line of beginning hepatic dulness on the right side, and the line of beginning gastric tympany on the left; it will be found that these lines are *higher* in the negro than in the white. If there be no error in these observations, the conclusion is inevitable that the perpendicular diameter of the interior of the thorax is thereby diminished. In a general way I will say that it is very rare that the physical signs are *absolutely negative*. There may be diminished expansion, a prominent clavicle with depression below and above, and asymmetry in movement, points of asymmetric percussion-sounds, vocal resonance, and fremitus, with more or less modification of the normal, rhythmic, clear vesicular murmur, with, in a considerable percentage of cases, adventitious sounds. The latter remarks are true to some extent in both races, but much more conspicuously so in the negro.

As to the greater abdominal and genital development, all one has to do is to see 300 or 400 negroes naked in a large bath-house, and then step through a door and see 75 or 100 white men in the same condition, to convince him of the correctness of this view.

The general muscular development, taken as a whole, is good in the negro; but the chest-muscles, and those below the elbow and knee, are deficient. I conclude, therefore, that the negro, as a whole, is inferior to the white in anatomic development and in the symmetric arrangement of systems and organs. That, therefore, there should be a correspondingly weakened function and predisposition to disease is apparent. That environment has a great deal to do with the causation of disease, both predisposing and exciting, there can be no question.

The question, therefore, remains: Have the white and negro convicts the same environment? I answer emphatically that they have. This is certainly true at the places whence the foregoing statistics were obtained. Hence the difference in mortality cannot be explained by a difference in environment.

The effects of prison-life, however well ordered, are, regardless of race, beyond all doubt detrimental to both mind and body. It affects the mind more in the white and the body more in the negro.

Now, just in proportion to the bad hygienic surroundings, both general and personal, will these effects obtain, particularly those on the physical condition. If these conditions are such as to be productive of disease they will operate more disastrously on the negro, both in morbidity and mortality. Therefore, it is under more or less unfavorable environment that the physical inferiority of the negro race becomes manifest. In certain statistics published by Colonel John G. Milner, it appears that in certain Northern prisons, in New Jersey, Pennsylvania, New York, and Ohio, and in the border State of Missouri, for a series of years the average white mortality was 1.55 and the negro mortality 5.05 per annum. The same may be said of the negro as a soldier. Among the United States white troops during the war the average

annual death-rate was 53.04 per 1000; and of colored troops 143.04 per 1000, or 1 to 2.69, a difference almost as great as that in the Alabama penitentiary. Given the same environment, the white man will have much the greater longevity. If the environment be bad, then the negro mortality will increase much more rapidly than the white. That prison-life, however well ordered, is always more or less unfavorable to life and health, the statistics of civil and military prisons prove. Why is this so?

The following, in my judgment, are the principal reasons, so far as civil prisons are concerned :

First—as to the convict himself. If he is guilty, there is not only a possibility but even a probability that there is some occult condition which we do not understand, inherited or acquired, that operates upon the mind in such a way as to suggest crime, or that cripples the moral inhibition that restrains crime, in either case affecting that mental and moral equipoise that inspires honesty and obedience to law, so that crime is committed not merely because of the common depravity of mankind, which in the individual criminal may be unrestrained, but because of this occult condition over which the criminal has no control. If there be truth in this conjecture, is it not logical to conclude that this occult condition would affect, in some way, the physical condition also? If the prisoner be innocent, then the horror of the situation—innocence in chains—would certainly act detrimentally upon health.

In both cases, whether he be guilty, the victim of some imperative power that forces him to crime, or the voluntary agent of total depravity; or innocent, the victim of circumstances or of perjury, the prisoner is a human being deprived of his liberty, with all that that means to him, socially, politically, religiously, and sexually, and the inspiration to work, to live, is almost dead. He becomes subdued and cowed, and his whole mental, moral and physical nature is more or less depressed and weakened. He therefore at once becomes more susceptible to disease; latent diatheses become active; existing mild diseases are increased in severity; the susceptibility to germ-infection is increased; and, finally, his ability to withstand disease of all kinds is more or less diminished.

Second. The change of hygienic surroundings, from a segregated to an aggregated relationship—from home, however humble, to prison, where he is thrown in contact with hundreds of his fellow-beings, breathing more or less the same air, becoming exposed to the infection of germs of various diseases, especially the tubercle-bacillus, submitting to a hygiene to which he has not been accustomed—in a word, to a changed environment altogether.

Third. The change of his personal hygiene in matters of clothing, diet, sleeping, drinking, and the kind and amount of work, etc.

These general remarks apply to all convicts, white and black, but the first affects the white more, and the negro least; the last two affect the negro more especially. That is to say, the negro has less capacity to accommodate himself to any new environments, particularly to bad ones. Finally, in the majority there occurs, sooner or later, a certain mental and physical resignation to the inevitable, that counteracts to a great degree the evils of prison-life; in other words a hygienic mental, moral and physical acclimation.

These conclusions are supported by the following facts: First. The greatest amount of morbidity and the greatest mortality are among those recently received. For example, the total deaths at the Pratt Mines, of State and County convicts for the two years ending October 1, 1888, were 80. Of these only 17 were received prior to January 1, 1886, and 63 from that date to October 1, 1888.[1] Also the total deaths of State and County convicts at the Pratt Mines, and State and County convicts at the walls, for the two years ending Oct. 1, 1890, were 132. Of these, 59 had been in prison more than one year, and 36 not more than six months.[2] Further, convicts are not classed up until they have been in prison for some time, and, therefore, the third and fourth-class convicts are mostly of those recently received. Percentage of mortality for each class—two years: First class, 3.68; second class, 6.49; third class, 8.61; fourth class, 13.79; $11 class (*i. e.*, those who work outside and for whom the contractors pay $11), 5.40.

Thus the mortality diminishes as the class is increased and *vice versa*.

The following is the percentage of morbidity represented in the days lost: First class, 13.80; second class, 18.47; third class, 19.58; fourth class, 41.38, or nearly one-half the total; $11 class, 6.79. It is a fact about which there can be no dispute, that the greater the number of convicts required to keep up a certain average, the latter depending upon the average term of the convicts, the greater is the morbidity and mortality. Hence the death-rate of County convicts is always greater than that of State convicts.

I think that I have shown in this paper that the negro, as a convict, so far as a low rate of mortality is concerned, is a failure. It would be interesting to enter into a full and complete discussion of the adaptability of the negro for coal-mining, but I forbear, inasmuch as this subject was thoroughly considered by me in a paper read before

[1] See Inspector's Report, p. 199.

[2] See Inspector's Report for 1890, p. 254.

this Association two years ago. I will say, however, that there is no doubt in my mind that the county convict system ought to be abolished altogether, and if not altogether, certainly so far as mines are concerned. And not more than 50 per cent. of the negroes sentenced to the penitentiary should work in coal-mines, and not even these unless there is adopted a system of prison hygiene that will permit of some open-air exercise, with sunlight.

In conclusion, I will submit that the race problem will be largely settled in the event of public works being established throughout the South—which means ready money for the negro; this means the profitable practice of prostitution, and this in turn means gonorrhea and consequent sterility; tuberculosis and other pulmonary diseases will do the rest.

SOME REMARKS ON THE PRACTICAL TREATMENT OF HEPATIC ABSCESS.[1]

BY JAMES E. THOMPSON, M.B., B.S.,
UNIV. OF LOND., F.R.C.S. ENG.,
PROFESSOR OF SURGERY, UNIVERSITY OF TEXAS; FELLOW OF THE TEXAS ACADEMY OF SCIENCE;
OF GALVESTON, TEXAS.

DURING the last year there came under my care two cases of hepatic abscess, presenting features of peculiar interest from an operative standpoint, and, on reviewing the literature on the subject, I was so struck with the wide difference of opinion in reference to treatment, that I determined to make a complete investigation of the causes, and, if possible, arrive at the methods which would present the least immediate mortality and the most perfect technique.

CASE I.—On September 7, 1892, C. B., an Irishman, aged fifty-three, a resident of Galveston for the last ten years, was admitted into the Sealy Hospital, under my care. Twenty-five years previously, when in Rangoon, he had contracted an acute dysentery, which remained chronic up to a few months before admission. He had repeated exacerbations, and four months before suffered from intense diarrhea, associated with pain and tenesmus, and occasionally with pain in the right side. On September 24th the patient came under my personal notice, and his condition was then as follows: He was slightly jaundiced, and much emaciated; the morning temperature was 101°, the evening temperature 102°; the pulse varied from 120 to 130; the tongue was red, raw, and coated. He complained of intense pain in the right side. Inspection revealed a great bulging of the right lower costal zone, and deficient respiratory movements in the right lower ribs. The liver was enlarged both upward and downward; the lower edge could be easily palpated, and ran in a curved line to the right, across the abdomen, touching in its course a point midway between the right costal margin and the umbilicus. Superficial dulness was absolute, and extended upward as high as the fifth rib in the mammary line, the seventh rib in the axillary line, and the ninth rib in the scapular line. There was no perceptible movement of the mass underneath the abdominal wall, nor could a friction-sound be distinguished. In the center of the abdominal swelling a soft spot could be felt, where an indistinct sense of fluctuation was perceptible. There was still diarrhea, and the stools were examined carefully for amebæ, but with a negative result. The fluctuating spot before mentioned was punctured with a hypodermatic needle, and thick, flaky pus flowed slowly through the needle. This on examination contained no amebæ, but was rich in crystals of leucin and tyrosin, with a few disorganized liver-cells. Unfortunately, no cultivation-experiments were made, so that it is impossible to say whether streptococci were present or not.

On September 24th, the patient being under the influence of chloroform and morphin, an incision, parallel to and two fingerbreadths below the costal margin, was carried over the most prominent part of the swelling. This was rapidly deepened, and adhesions were soon discovered, uniting the liver and the abdominal wall. A scalpel was passed into the abscess-cavity, and an incision made in the walls large enough to admit two fingers. The pus, which escaped with difficulty on account of its thick, glairy nature, contained numerous pieces of disorganized bile-stained liver-substance, which, when floated in water, showed the interlobular vessels, with parts of two or three hepatic lobules hanging around them. The cavity was thoroughly washed out and drained by a large glass tube sheathed with rubber. The wound was packed with iodoform-gauze, and dressed antiseptically.

The after-treatment of the case was very tedious. In spite of the large drainage-tube, the thick, glairy pus flowed but slowly, and it was found necessary to introduce two tubes, side by side, and irrigate the cavity through them. This acted much better, and the case progressed fairly favorably for three or four weeks, when it was resolved to enlarge the opening to treat the cavity by direct swabbing with sponges. This was done on October 31st, and the recesses of the cavity were gently and thoroughly curetted and swabbed until they were as clean as a healing ulcer. During the curetting the bleeding was very slight and never interfered with a perfect view of the cavity. The cavity was then packed with iodoform-gauze. Still, in spite of careful dressing, no improvement resulted. A copious glairy purulent discharge returned, and the patient contracted a persistent and troublesome diarrhea, which caused great emaciation. He slowly but surely sank, dying on January 7, 1893.

CASE II.—Adolphe B., aged sixty-three, a native of France, who had lived in Galveston for three years, was admitted under my care on February 18, 1893, complaining of pain in his abdomen. He was a man of slow intelligence, and little could be elicited either as to his previous history or as to his present condition. He complained vaguely of pain in the right side of the abdomen, but could not

[1] Read before the Southern Surgical and Gynecological Association, at New Orleans, 1893.

definitely locate it. A large reducible inguinal hernia was present on the right side, but this evidently had no bearing on the case. The temperature was of a remittent type, without rigors, reaching in the evening 102.8°. Inquiries were made as to malaria, and the blood was several times carefully examined, but with negative results. The pain still continued, and in the course of some seven or eight days declared itself more definitely in the lower part of the right chest. Examination of the lungs revealed nothing. There was no increase of liver-dulness, either upward or downward, and no tenderness on pressure over the right lower costal zone. The patient denied ever having had dysentery, and at this time there was no evidence of it; but later on, when the diagnosis was certain, I learned that he had been treated for amebic dysentery during the previous summer.

The temperature and pain still persisted, and in a little time definite physical signs became apparent. The right lower costal arch became fixed, not moving with respiration; it bulged somewhat, but not perceptibly more than the costal arch of another thin, healthy patient who was examined for the sake of comparison; but an important sign appeared in a spot of edema in the anterior part of the seventh intercostal space. The needle of an aspirator was inserted at this spot, and when at a depth of one and a half inches pus was obtained. This was thick and curdy, and contained numerous amebæ possessing active movements. Operation was performed on the following day, the patient being under the influence of chloroform.

I made a four-inch incision along the line of the seventh intercostal space, having its center over the edematous spot. This was deepened, and the anterior extremities of the seventh and eighth ribs and parts of their costal cartilages were excised, the pleural cavity being opened in the process. No retraction of the lung occurred, but the upper surface of the diaphragm projected into the wound. An incision parallel to the skin-incision was now made through the pleural covering of the diaphragm, and this was raised up with the handle of a scalpel and stitched accurately to the parietal pleura, thus shutting off the pleural cavity from that of the wound. The diaphragm was now incised, and a few strokes of the knife revealed adhesions between its under surface and the convex surface of the liver. A trocar and canula were thrust into the abscess-cavity, and a scalpel passed along the trocar, making an opening into the abscess capable of admitting two fingers. The pus, which was thick, flowed slowly through the opening. About fifteen ounces of purulent fluid were evacuated, which contained masses of liver-substance and myriads of amebæ. The opening was enlargd carefully until a sponge was inserted, by means of which every crevice was thoroughly cleansed. Two large, long, glass drainage-tubes, sheathed with rubber, were inserted into the cavity, and the operation-wound closely packed with iodoform-gauze. The effect of the operation was immediate, and the patient soon recovered from his collapsed state. The cavity was irrigated continuously with boric-acid solution from the first, and there was never any trouble with the apparatus.

On the fifth day after the operation, as the pus that came away still contained living amebæ, I substituted a solution of quinin sulfate (1:1000) for the boric acid. The effect was marvellous: the temperature fell, remaining practically normal thereafter; the pus diminished in quantity, and for a few days contained dead amebæ, but after this what little pus was discharged contained no amebæ. The wound healed, and the patient is now entirely cured.

The diagnosis of hepatic abscess may be the easiest possible, or beset with numerous difficulties. Occasionally we can only suspect its existence from such symptoms as pain and elevation of temperature, the other signs being bulging of the lower costal zone and dyspnea; enlargement of the liver may be imperceptible, even to the most accomplished diagnostician. It is in the latter cases that most of the difficulty of diagnosis arises, and it would be better in cases in which there is persistent elevation of temperature and pain in the region of the liver, if the lungs are free from disease, to proceed to puncture of the liver with an exploring-needle. Early and complete exploration is a harmless procedure, and would be the means in many cases of discovering abscess-cavities before they had attained a great size. But this exploration is occasionally fallacious, for an abscess-cavity of fair size may be present and puncture will fail to detect it. This has often occurred, and is usually due to one of two reasons:[1] either because the contents are too thick to run through the needle, due to caseation of the pus, or due to the naturally thick nature of the pus in the early stages of amebic abscess, or[2] the cavity has been missed by the needle. This occurred in Quénu's case;[3] the liver was exposed by an abdominal section, and explored in all directions without finding pus. A few days afterward the autopsy revealed an absces-cavity containing two liters. Even when pus is discovered by the aspirator, the diagnosis from other inflammatory affections in the neighborhood, such as "basal pyothorax" and "subphrenic abscess," may be difficult; and although in the majority of cases by careful attention to detail we can avoid such mistakes, still, occasionally, even in the hands of skilled diagnosticians, such faults have occurred.

The physical signs of the three affections are very similar, and in many cases those of subphrenic and hepatic abscess are identical. Careful microscopic examination of the pus will sometimes clear up a

[1] Dabney: Study of Hepatic Abscess. American Journal of the Medical Sciences, No. 244, p. 144.

[2] Councilman and Lafleur.

[3] Quénu: Société de Chirurgie, 1891. Quoted by Leblond: Abcès du Foie. Paris, 1892.

doubtful case, as the presence of liver-cells is always conclusive of hepatic abscess.

If pus be discovered, and its hepatic origin found, the next question that presents itself to a practical surgeon is as to operative interference.

Now the presence or absence of adhesions of course makes a great difference in the immediate mortality, for, if present, there is no danger of infection of either pleural or peritoneal cavity. Adhesions can never be diagnosticated with absolute certainty, but there are certain signs that, when present, render it extremely probable that they exist. These are: the presence of edema in the abdominal or thoracic wall; absolute fixation of the liver to the parietes, as shown by its non-descent during inspiration; and the presence of pus at a small depth from the surface. Nevertheless the absence of adhesions ought not to influence a surgeon in the slightest degree as to the propriety of speedy evacuation of the abscess-cavity. One knows the rapidity with which some of the abscesses form, and their liability, after reaching a certain size, to burst into various cavities and organs. Therefore, as even twenty-four hours may be too long a time to wait, no surgeon should hesitate to proceed to evacuation because no adhesions exist. It seems to me an axiom that "in abscess of the liver, whenever the diagnosis of pus is made, the only proper treatment is by early and large incision."

On reviewing the older methods of operation, it appeared to me that they group themselves into two main divisions: 1. Those in which the abscess-cavity was treated by aspiration, or a modification of this in which various forms of trocars and canulæ were employed. 2. Those in which a more or less free incision was used.

In considering the first class, we are necessarily struck by the fact that aspiration has been credited with many successes. This is, of course, not surprising, as it is the result of experience that aspiration of abscess-cavities elsewhere has also resulted in some successes; but, because we get an occasional cure by aspiration, does it follow that this must necessarily be the proper method? Do we follow such a line of reasoning in tuberculous cavities, and in pyothorax? When one considers the thick character of the pus in most hepatic abscesses, it can only be a matter of wonder that aspiration has been as successful as is reported. The introduction of a large trocar and canula is less objectionable, but even here we run a great risk, for although for a time the sides of the puncture press closely upon the canula, and prevent extravasation, in a short time pus may escape alongside the canula and infect the peritoneal cavity. To avoid this contingency, Macleod [1] arranged an ingenious apparatus whereby the canula was withdrawn and a rubber-drainage tube, tightly stretched, left in its place. The drainage-tube, which had side openings only at the inner end which lay in the abscess-cavity, was released, and resuming its normal diameter completely filled the channel previously occcupied by the canula; the rubber pressed on the sides of the wound, and prevented any extravasation into the abdominal cavity. This operation has been very successful in Macleod's hands, and is certainly the best of its class.

In the second class of operations, in which an incision was employed, we find many curious methods, some of them carefully guarding against serous infection, others blindly ignoring all surgical principles. Recamier [1] opened the abscess in two stages. His incision went through all structures as far as the parietal peritoneum; then, packing the wound, he waited until adhesions had formed, when the abscess-cavity was opened. Begin [2] cut through the parietal peritoneum; and then, placing an antiseptic plug in the wound, waited until adhesions had formed around the opening. Another crude method was to incise down to the parietal peritoneum, and then to complete the process gradually by caustics placed in the wound. Adhesions formed, and in many cases the abscess opened spontaneously.

Little [3] planned an operation, the chief merit of which consists in its boldness. Having determined the presence of pus, a bistoury was passed along the needle of the aspirator, and, in defiance of anatomic conditions, a free opening was made, through which the abscess was evacuated. The number of successes obtained by this method is marvellous, and can only be explained by the presence of adhesions in the majority of the cases operated on. Defontaine [4] found five cases in which this method had been used and in which it was proved that no adhesions existed. Of these, three died, the cause of death in two being peritonitis. He said, in reviewing this method, that a single death from this cause ought to be a death-blow to the operation. The more scientific operations are of recent date, and, like those for the radical cure of hernia, depend more on anatomic knowledge and surgical skill than on chance. Whether the abscess lies under the thoracic or abdominal walls, the incision is made methodically through all of the layers, and each cavity is dealt with in such a manner as to shut it off from all chance of infection.

I. *Cases in which the enlargement of the liver is abdominal, and no adhesions exist.*

For a long time it was doubted whether, with any

[4] Leblond: Loc. cit., p. 98.

degree of certainty, the liver could be stitched to the abdominal walls, but when the fact was demonstrated a way was at once opened for the treatment of both hydatid cysts and hepatic abscesses. Horner[1] first performed the operation, and was soon followed by Bouilly; and then McLane Tiffany conceived the idea of detaching the edges of the parietal peritoneum for some distance, and uniting them to the convex surface of the liver. If this separation is done with care, the two edges of the peritoneum hang like a curtain, and can be sutured to the liver, their length of pendulousness allowing free respiratory movement without dragging on the stitches.

When the hepatic enlargement is abdominal, we open the cavity and expose the liver. The organ is carefully examined and inspected, and in one case[2] the presence of a second abscess was determined. The peritoneum should be detached from the edges of the incision for some distance, and united by points of suture with the surface of the liver, leaving a sufficiently large space for the proper evacuation of the abscess-cavity. The sutures require careful manipulation, and there should be at least two concentric rings. The peritoneum should also be long enough to allow for the respiratory movement of the liver without undue dragging on the sutures. Occasionally the abscess has been evacuated before applying the stitches. In this case the sutures should pass through a fair thickness of liver-wall, but should not touch the abscess-cavity. It is, however, better, unless there are urgent reasons to the contrary, not to open the abscess-cavity immediately, but to aspirate and allow time for adhesions to form before proceeding to thorough evacuation.

II. *Cases in which the enlargement of the liver is upward toward the thoracic region.*

In these cases the transpleural incision is undoubtedly the best. First proposed in 1886, by Knowsley Thornton,[3] it has since been successfully carried out by many operators.[4] Thornton excised the seventh and eighth ribs, opened the pleural cavity, elevated the diaphragmatic pleura and stitched it to the parietal pleura, incised the diaghragm, and opened the liver-abscess without taking any precautions against peritoneal infection. Terrier planned what must be considered a perfect operation. An incision eight centimeters long was made in the eighth intercostal space, the ninth rib resected for an extent of four centimeters, the pleural cavity opened, and the diaghragmatic pleura stitched to the parietal pleura. The diaphragm was incised and the lips of the wound united to the liver by silk sutures, thus forming a channel passing from the surface of the body which had no communication with either pleural or peritoneal cavity. The abscess was then opened with a bistoury and drained. This method of Terrier[1] is undoubtedly the most perfect. It has a faultless technique, and has yielded good results.

Some objections may be raised to this transpleural method on account of the immediate danger of collapse of the lung, and the more remote danger due to infection of the pleural cavity. Collapse of the lung is not likely to occur. It was not noticed in Terrier's case or in my own, and further, in many wounds of the chest the lung fills the pleural cavity, in spite of a large opening. Even if collapse did occur, I think it would be temporary only, unless fluid collected in the pleural cavity. The later dangers, such as pyothorax and pneumonia, depend upon the completeness with which the technique of the operation is carried out.

In conclusion, I should like to mention a few points on the treatment of the cavity after the contents have been successfully removed.

It is often exceedingly difficult to obtain free drainage, even when large tubes are employed. In some cases even swabbing the walls of the cavity is ineffectual, and these cases are practically hopeless, owing perhaps to inherent tissue-weakness. I tried curetting in one of my cases, and although I removed, as I thought, all necrotic tissue, still in a few days the cavity was as bad as before. Continuous irrigation often affords a means of efficient removal; but the tubes have an aggravating habit of being blocked, necessitating frequent changing and cleaning.

Irrigation with a solution of quinin sulfate—1:1000—was in one of my cases remarkably successful, and although the improvement may have been a coincidence, and not a *post hoc ergo propter hoc*, I think that in cases of amebic dysentery at least it deserves a fair trial.

THE INTERRUPTED HIGH-VOLTAGE PRIMARY, OR MIXED, CURRENT.

By GEORGE J. ENGELMANN, M.D.,
of St. Louis.

The interrupted high-voltage primary or mixed current is one of the results of experiment with my new independent interrupter, devised for my faradic apparatus, but to be used also in connection with any galvanic and faradic apparatus; it has proved to possess an individuality peculiar to itself and of great physiologic efficiency, so that I am convinced of its therapeutic value and present it for the consideration of the profession.

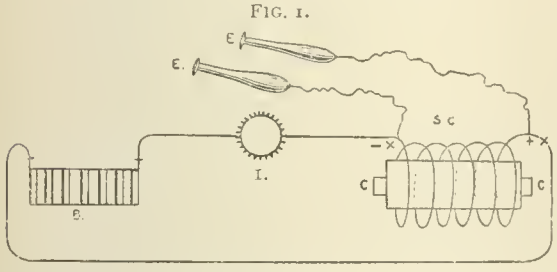
[1] Terrier: Observ. par Dagron, Soc. Anat., 1890, p. 44; Leblond, loc. cit.

This current, which I term the *interrupted high-voltage primary*, or *mixed*, current, is obtained by the interruption of the galvanic flow passing through the secondary coil of the faradic apparatus, and is taken from the terminals of that secondary coil, here used as a primary, which is of higher voltage, of many more winds and greater resistance than the ordinary primary in medical induction-instruments.

The current so obtained is hence not precisely identical with the primary faradic, and may properly be termed a *mixed* current, if not an *interrupted* primary of higher voltage.

A well regulated, controllable interruptor is above all necessary.[1] Any galvanic battery may be used; one pole is connected with the interruptor, and through this to one of the terminals of the secondary coil of the faradic apparatus[2] (the binding-post from which the secondary current is taken); the other pole of the galvanic battery is connected directly with the remaining terminal of the secondary coil, and with these same two terminals the rheophores carrying the electrodes are connected.

FIG. 1.



B. Galvanic battery. I. Interrupter. S.C. Secondary coil —X and +X. Terminals of coil. C. Core and primary coil. E. E. Electrodes.

A current so produced combines the characteristics of the galvanic and the induction flow; it has the same galvanometric quantity and the same chemic effect as a simple galvanic current of the same intensity, or, from the same number of cells applied in the same manner *plus* the voltage and the physiologic effects obtained from the winds of the coil; coil and patient being connected in multiple, the resistance is diminished and the current increased, but increased in voltage rather than ampèrage—converted, I may say.

The *physiologic effects are peculiar*, and differ materially from those of any other form of electricity in medical use, the current combining, as it were, the quantity and chemic effect of the galvanic with the voltage of the faradic; the effects resemble most nearly those of the primary faradic, but are more powerful and indicative of greater quantity, most marked in their *action upon muscular fiber*, which is affected by this *as by no other form of electricity*.

A variety of effects are produced by the use of different current-intensities and different coils; yet while this current will undoubtedly be of distinct value in certain nerve-lesions, it will prove pre-eminently a *muscle*-current, as it contracts the muscle most perfectly, acting upon every fiber in the most marked manner, like a powerful interstitial or intercellular massage.

The character and effect of the current depend upon the following elements, which must be noted, as it is by a variation in these factors that the varying therapeutic results are obtained:

1. The number of cells or intensity of the primary battery-flow.
2. The resistance and number of winds of (the secondary) coil.
3. The number of interruptions.
4. The position of the secondary coil in reference to the core and primary.
5. The character and location of the electrodes.

1. The number of cells used or the intensity of the primary battery-flow determines the galvanometric measure and chemic effect; these being the same as from an ordinary galvanic current without insertion of the coil and applied in the same manner, it is evident that the character of the current must in a measure depend upon this factor; but as voltage and induction-effects are prominent, the number of cells to be employed is determined, not by the chemic effect to be produced, but by the coil to be used. Only one cell can be employed in connection with a short coil, the number of cells being increased with the resistance and number of winds in the coil; but more than ten or twelve cells, if in good condition, can hardly be used to good advantage, even with the long fine coils, at least on healthy tissues.

2. It is the coil preëminently which determines the character and effect of the current,[1] the resistance and

[1] For slow interruption, simple muscle-stimulation and massage, the interrupter ordinarily connected with a complete galvanic apparatus may be used, or, for rapid interruption, a commutator attached to the shaft of a motor, but precision is necessary, and ere long the perfected instrument, which has been devised and constructed by Messrs. Waite & Bartlett in accordance with my suggestions, will be in the hands of the profession, and accurate work, record, and comparison of results will then be possible.

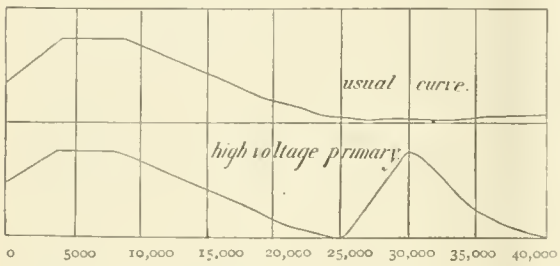
[2] Not every faradic apparatus will answer, as most instruments have but a single coil and this may give a very unsatisfactory mixed current. To obtain the various therapeutically serviceable phases of this current an induction-apparatus, with a graded set of coils, is necessary; but if it has but one secondary coil it should be of approximately 1800 W. and 13 ohms R., or of about 800 feet of 22 wire, as this develops the most generally useful form of the interrupted high-voltage current, the painless muscle-permeating current.

[1] In speaking of *the coil*, I invariably refer to the *secondary* coil of the faradic apparatus, in position on the instrument, *used as a primary* in this circuit.

number of winds materially varying its physiologic value, but not in precisely the same manner as when used as a secondary in the faradic current proper. The faradic current from a coil of high voltage, or many winds, has *least* quantity, whilst the mixed current from this coil is of necessity one of *greatest* quantity.

The lower the resistance of the coil and the less the number of winds, the more powerful the induction-effect and the less the quantity of the primary galvanic force to be employed: No. I coil (Engelmann), 0.8 ohms R., 528 winds, has an effect, both motor and sensory, too powerful for therapeutic use, even with one single cell of the weakest Leclanché.

Fig. 2.



No. II, the medium coil, 13 ohms R., 1750 winds, with one cell from any galvanic battery, produces the most satisfactory, deep, muscle-contracting currents, permeating every fiber. This is, *par excellence*, the coil which gives value to the current, and it is remarkable how completely it can be confined to a distinct muscle by the location of the electrodes; whilst permeating its fibers it does not seem to radiate beyond.

For the developing of the most satisfactory results, the number of cells used must be increased with the resistance and number of winds in the coil:

	Feet.	Wire.	Winds.	Number of cells found to be effective.
For a coil of	1500	36	4,000	4 to 5
" "	3000	36	7,000	7
" "	4500	36	10,000	9 to 11

By longer coils muscular contractions are likewise produced; but these are more painful, and the chemic effects of the galvanic current begin to assume prominence; these should prove efficient for other therapeutic purposes, when more marked galvanic effects are called for.

3. Change of relation between the secondary coil and the primary coil and core, *i. e.*, the moving to and fro of the coil on the scaled slide, varies the intensity of physiologic effect. This variation of intensity is similar to that of the primary faradic, but differs in some features; if coils of low electromotor force are used, the intensity of physiologic effect is increased by a sliding out of the coil away from the core; this is most marked in the coil of fewest winds, coil I, 528 winds; somewhat less so, but still very decided, in coil II, 1750 winds, 13 ohms R.; coils of higher E. M. F., longer; fine-wire coils, on the contrary, *weaken* the current-effect by the drawing out of the coil, or the moving away from the core; this is true, even of the coil of 1500 feet, or 4000 winds, and of the muscle-coil of fine wire in multiple, 6500 winds, and only 4 ohms R.

The true primary coil of the apparatus is ignored in these experiments, and its terminals are not connected. When this is done it acts as a damper, like the copper tube of Duchesne, to weaken the current.

4. The number of interruptions, or the rates of vibration, control the physiologic effect of this current, as they do that of the faradic, whilst the chemic and galvanometric action is affected but little and that in a contrary sense.

Interruption and alternation affect the physiologic action of this current in the same manner, but I shall speak only of interruption, pure and simple, as it is the interrupted primary which will prove of greatest therapeutic value, this being more agreeable, less painful and harsh than the alternating, and equally, if not more, efficacious as a muscle-contractor, so that the alternating primary will only be used when it is of importance that all chemic action be avoided. Both currents, interrupted and alternating, will respond to certain therapeutic indications; but as a simple muscle-contractor the more irritating and disagreeable alternating will find little favor as compared with the interrupted current; both, however, respond in precisely the same way, as regards physiologic effect, to variation in the rate of interruption.

Other conditions being equal, the same number of interruptions and alternations produce the same effect, *i. e.*, 10,000 interruptions have the same comparative effect as 20,000 alternations upon the current. As in the secondary faradic, the effect of the current increases with the rapidity of interruption from 1 to 2500 or 3000 per minute, and, after attaining a maximum effect, decreases with increased rapidity of interruption until a rapidity is reached with which all sensation ceases. Though the galvanometric effect is unchanged, the chemic effect increases; the more intense the current the greater the number of interruptions necessary to completely annul its effect.

Coil I, heavy, with one cell, causes powerful and painful contractions, too violent for general use with the ordinary rate of interruption; yet it ceases to have any effect, or to be felt, with 14,000 interruptions per minute (this when full in, over core, with small sponge electrodes to upper and lower

arm, the effect depending greatly upon the moisture of the electrodes and the pressure upon them).

The 10,000-wind coil, 4500 feet of 36 wire, 11 cells, sponge electrodes to upper and lower arms, ceases to be felt at 25,000, whilst if only 7 cells are used, the same result is accomplished by 20,000 interruptions per minute.

The general law mentioned, of increase of effect with increase in rapidity of interruption, then decrease with still greater rapidity, holds good with one curious exception, true of the secondary faradic, as it is of the interrupted, or alternating high-voltage primary; and this interesting phenomenon, which merits a more thorough discussion elsewhere, I must here at least note: it is that currents from certain coils, as far as I have observed, from 5000 to 10,000 winds, 36 wire, under certain conditions, after passing that rapidity of interruption at which they cease to be felt, *reappear* with greater rapidity, again *attain the previous maximum*, to again lose all effect with still greater frequency of interruption. In place of the simple rise and fall, there is a second shorter and additional curve of rapid rise to the previous maximum and fall to zero.

The 36-wire coil of 10,000 winds, with 11-cell primary galvanic force, ceases to be felt with 25,000 interruptions, then reappears, regains its previous efficiency at 30,000, and again weakens as the interruptions grow more rapid, to completely fade away as they attain a speed of 40,000 per minute; if fewer cells are used with the same coil, precisely the same phenomenon is observed, the same effects being produced by lower rates of interruption as the current is weaker.

5. That the character of the electrode, which determines penetration and surface-resistance, influences this current, as it does both galvanic and faradic, need hardly be mentioned; material, size, degree of moisture, location, and pressure upon the electrode, all serve to vary the sensation and effect of the current, and must be considered as determining factors.

This interrupted, high-voltage primary current possesses an individuality which must secure it a distinct place as a therapeutic agent; by blending the quantity and chemic action of the galvanic with the voltage and mechanical effects of the faradic we are enabled to produce peculiar effects; yet both are so modified that the resultant differs from a simple combination of these two forms of electricity. It differs from the painful interrupted or alternating galvanic as it does from the ordinary faradic, the secondary or induced current, and it will be resorted to when deep, penetrating effects are desired and when permeating muscle-currents are indicated; it will act, I believe, in those cases in which faradization fails. No other current, with such penetrating power, can be so localized and grasp every fiber of a muscle as does this.

Therapeutic effects I have not, as yet, been able to test, and cannot speak of its action upon muscle in central and peripheral lesions, but physiologic experiment indicates the powerful influence of this current, from proper coils, upon contractile tissue, and it is in this direction that investigation must first proceed.

In conclusion, a word of caution to the operator: Care must be exercised in the selection of battery-force and coils until a knowledge of the current and its effects is obtained. It is best to begin with the use of the lowest current-intensities, or the fewest galvanic cells which will take effect through the coil employed, or to use the number of cells here indicated as suitable for the various coils, varying the current by the pushing in or out of the coil, as the case may demand; when familiarity with the current has been acquired, this may be varied by variation in the galvanic flow for certain effects. It must be remembered that coils of low E. M. F., heavy coils of few winds, must be *drawn out* to *increase* the physiologic effect, whilst coils of higher E. M. F., the long, fine coils, vary less and in a different manner; these *weaken* by *drawing out*. It is also important to remember that the current-effect increases more distinctly than that of the faradic, with increase in the rapidity of interruption up to 3000 per minute, and, after attaining a maximum, gradually decreases with increased rapidity, decreasing in proportion to the current-intensity; the stronger the current the greater the number of interruptions necessary to reduce it.

A note must be made of the peculiar effect of fine-wire coils of from 5000 to 10,000 winds, which again attain a brief maximum intensity with increase of interruption after having been obliterated by a certain rapidity.

It is evident that this current is one easily obtained if a proper interrupter and a coil of suitable construction are available, as a single galvanic cell, Leclanché, Gonda, dry or red acid, will answer for use with the muscle-coil, the galvanic battery, or a larger number of cells, being needed only with the longer coils, which are not as generally useful.

I trust that an earnest trial will be given the interrupted high-voltage primary, which merits a place in our therapy, if only for its permeating muscle-effects, and I am convinced that therapeutic use will soon demonstrate the greater range of this efficient current.

The International Medical Magazine will hereafter be edited by Dr. H. W. Cattell, under the supervision of Dr. John Ashhurst, Jr., and Dr. James T. Whittaker.

SUPRA-PUBIC CYSTOTOMY.[1]

By B. W. TAYLOR, M.D.,
of Columbia, S. C.

I. FOR VESICAL CALCULI.

It appears that supra-pubic cystotomy was first performed by a French surgeon, Peter Franco, in 1541, upon a boy who had a large calculus, very prominent above the pubes, but which could not be pushed down in the bladder so as to be felt in the perineum. When we take into consideration that the bladder in the child is much higher than in the adult, we will perceive why the calculus was so easily felt above the pubic bone. Notwithstanding the success attending this case, the operation was not favorably thought of by the profession, and it was not until 1580 that François Boussett again revived this operation and saw the necessity of distending the bladder with a bland solution and compressing the penis to prevent the escape of the injected fluid. He also retracted and protected, with the forefinger, the peritoneal fold during the incision of the bladder. Thus two important steps in the operation were discovered, and from that day to this these precautions have been carried out.

Fr. Côme, who lived about 1779, repeatedly performed this operation with success by passing into the bladder a sound with a concealed dart, the finger then being introduced into an incision made in the abdominal wall just above the pubes, and the sound being felt against the finger, the dart was protruded. A bistoury was then passed along the dart as a guide, the opening was enlarged and the finger introduced into the bladder. Côme also recommended the perineal incision for the purpose of drainage in cases of the supra-pubic operation.

The London surgeons also performed this operation successfully, but the danger of wounding the peritoneum, which was much feared in those days, most probably caused the operation to be given up.

In 1878 Dr. Garson discovered that by distending the rectum with an inflated rubber bag and at the same time distending the bladder with fluid, the latter could easily be opened without endangering the peritoneum, which would thus be about two inches above the pubic bone.

At first this discovery did not seem to favorably impress the profession; but several years afterward Prof. Petersen, of Kiel, performed several operations and showed the advantages of rectal distention.

We have thus traced the evolution of the operation as now performed, antiseptic precautions, of course, being rigidly carried out.

We will now compare the results of the several operations for the removal of stone from the bladder.

[1] Read by title before the Southern Surgical and Gynecological Association, November, 1893.

The mortality of litholapaxy, as given by Sir Henry Thompson in 1890, was a little over 3.5 per cent.; and by Keyes in 1885 as 3.7 per cent.

It appears at present that litholapaxy gives better results than any other operation for stone, but it requires more skill and experience, and the instruments required are expensive. Litholapaxy will therefore seldom be performed except by specialists.

In perineal lithotomy the possible complications that may occur during the operation, but which are avoided in supra-pubic lithotomy, are:

1. Failure to enter the bladder, especially in children.
2. The incision of the body of the bladder in adults with large calculi.
3. Wounding the rectum.
4. Rigidity of the neck of the bladder.
5. The enlarged lobe of the prostate interfering with the seizure of a stone in an abnormal position.
6. Failure to find the stone.

The possible after-complications of perineal lithotomy that are avoided in supra-pubic lithotomy are:

1. Retention of urine.
2. Epididymitis.
3. Orchitis, due to wounding the seminal ducts, or subsequent inflammation near their orifice.
4. Incontinence of urine, which McGuire says never occurs in the high operation.
5. Impotence and sterility.
6. Terminal fistula.

The complications and accidents peculiar to supra-pubic lithotomy are:

1. Rupture of the bladder during preliminary distention, which I think must occur but rarely with skilled operators.
2. Infiltration of the wound from bad drainage. As to this, McGuire says: "It is more complete than in drainage after section through the perineum. If hemorrhage occurs it can be seen from whence it comes and it can be more easily controlled than in perineal lithotomy."

The operation is simple and far less dangerous than any cut in the perineum. If a fistula is left it is above the pubes and is not constantly leaking. Lydston mentions a case in which a tube was introduced in the bladder through the perineum and another through the supra-pubic opening, drainage taking place where there was the least resistance, namely, above, and not one drop of urine passed out through the perineum.

Cabot lays down the following cases as unsuitable for litholapaxy and perineal lithotomy:

1. Large and hard stones.
2. Stones with a nucleus of a foreign body too hard to crush.
3. Encysted stone.
4. Ankylosis of the hip.

5. False passage of the urethra.

Up to the present time, although supra-pubic lithotomy has so many advantages over the perineal section, yet the published statistics give the latter a lower mortality. This, I think, is in part due to the unwillingness of surgeons to give up lateral perineal incision, which has given such results as Freyer has achieved, of operating on 143 boys without a death. Assendelft, a Russian surgeon, has performed supra-pubic lithotomy on 102 patients, varying in age from five to twenty-eight years, with 2 deaths. These figures, of course, do not give the mortality of patients of a more advanced age, for whom the death-rate is necessarily greater.

I will now give the histories of two cases I lately operated on.

Case I.—J. W. T., nineteen years of age, had attacks of renal colic for six years. About two years before the operation he was very ill for several days, when a calculus passed into the bladder and a free discharge of pus from the penis. It was a short time after this that symptoms of stone in the bladder developed. The supra-pubic operation was performed with the usual technique. The peritoneal fold was lifted up with the finger. The rubber tubes placed in the bladder were removed early, as they caused much irritation. Some urine passed from the penis in eight days, the greater part being passed through the wound until the eleventh day, when the incision closed up. There was no rise of temperature.

Case II.—L. A. W., forty-three years of age, had attacks of renal colic for seven years, some of the stones being voided with the urine. Four years before the operation the first symptom of stone in the bladder showed itself. The man was operated on by the supra-pubic incision. The peritoneal fold was never visible. He had no pain or rise of temperature after the operation, and was allowed to go to his home, twenty-five miles away, in twelve days. He urinated naturally in twenty days, and in thirty days the wound had healed entirely. He has been well ever since.

In appropriate cases I would advise closing the bladder at once by the interrupted Lembert suture of fine silk, the incision being held close together by a suture of silk at each end of the wound in the bladder. These stitches, of course, must not penetrate the mucous membrane of the bladder. A small drainage-tube is introduced at the lower part of the parietal wound, which is then closed. Remove the tube in forty-eight hours. The urine is drawn off by a soft catheter, if necessary, no other provision for its removal being required.

II. FOR ENLARGED PROSTATE.

The operations of Gouley and Mercier for incising or removing a portion of the bar in senile enlargement of the prostate without opening the bladder has been given up by most operators on account of its dangers and the uncertainty of the results.

The object of all operations performed in cases of hypertrophy of the prostate is to effect free drainage and give the bladder complete rest. Then, again, the obstructing portion of the prostate is removed, so that, when the wound heals, the patient can again perform micturition normally.

Now, when we drain the bladder through a perineal wound, the urgent painful symptoms are relieved only so long as the opening remains unhealed. When it closes, the same symptoms, after a time, return. This operation fails to relieve the existing obstruction in a large number of cases. McGill, of Leeds, says that in only three among twelve cases, in which he operated by the supra-pubic method, would it have been possible to remove the growth through the perineum.

McGill was the first to show the great advantage of the supra-pubic operation for removing prostatic obstruction, and the series of cases published by himself and Keyes, of New York, has caused the operation to be considered superior to the perineal section.

McGill says "that the severity of the symptoms in a case of hypertrophy of the prostate bears little or no relation to its apparent size, as felt through the rectum; and it is also well known that a considerable number of men of fifty-five years and upward have prostates of abnormally large size, though of these only a certain proportion, say 50 per cent., suffer from urinary symptoms. This strange difference depends on the point at which the organ is enlarged. Prostates projecting toward the rectum and perineum cause no urinary trouble, while severe symptoms may supervene when the prostate, on rectal examination, is apparently of normal dimensions."

When, therefore, we consider that, before opening the bladder, it is impossible to say what is the condition of the entire vesical projection, the perineal operation appears to be most uncertain in its result.

I shall not describe the various prostatic growths, but will refer to only one variety, as the case I report was of that character, viz., a uniform circular projection, surrounding the internal orifice of the urethra. It surrounded the urethra like a collar and projected for a variable distance into the bladder. McGill says that, when the bladder contracts on its contents, the contained fluid is forced on the projecting prostate and the urethral orifice is closed. The mechanism is the same in all varieties except one. The patient, finding he is unable to relieve himself, ceases to strain and the urine flows away in a full stream. After a time the bladder still contains urine, but no more can be forced out; then begins self-catheterism, which, in many

cases, is all that is needed. McGill says that when in these cases an operation is demanded the supra-pubic method is superior to the perineal for the following reasons:

1. It is more generally applicable.

2. It can be performed with greater precision and completed with greater certainty.

3. It insures complete and most efficient drainage.

4. It is equally safe, although there are no statistics available.

As to the final results, we may say that even in cases in which the prostatic retention was of long duration, there are many patients in whom the bladder has, since the operation, been able to expel its contents. This has occurred even in cases in which self-catheterism had been practised several times a day for years.

Then, again, there are cases in which it is necessary to keep the supra-pubic incision open for the rest of life. This fistula, when reduced to the size of the natural urethra, does not permit leaking or dribbling of water, unless the bladder is allowed to become too full. Dr. McGuire wrote me the following with regard to the after-treatment of the case I will later report:

"In the formation of an artificial urethra for prostatic obstruction, I let the wound heal until it admits a No. 8 catheter, American scale; then a plug should be introduced into the tract and retained there by a band passed around the pelvis. When the patient wants to relieve himself the plug is removed and the man voluntarily expels the urine through the opening. Immediately afterward the plug is replaced and worn until the desire to make water returns. It is not necessary that it should be worn constantly, if it creates any irritation, but I have seen the artificial tract close up in a night.

"To siphon the bladder out with a catheter will produce atrophy of the bladder; and unless this exists before the operation, it is not necessary to use a catheter or any tube to draw off the water. He ought to keep open, the rest of his life, the artificial urethra."

I will now give the history of a case:

Mr. R., aged seventy-six years, has had piles for forty years. About six years ago he had retention of urine and was sick six weeks, the urine being drawn off by catheter a part of that time. He then remained comparatively well for a year, when trouble again occurred. It was not until three years ago that it became necessary to draw off his urine daily. During this time he has twice had retention of urine, with painful distention of the bladder. It was found impossible to introduce a catheter until the bladder was aspirated. The calls to urinate during the last three months have at times been as frequent as every hour, with straining and protrusion of the piles, which had to be replaced by the hand with a good deal of pain. For one month before the operation it was found necessary to keep a No. 8 silver catheter in the bladder most of the time, as it was impossible to use the soft rubber catheter, which he had up to that time introduced. For a long time he refused to be operated on, but as we expected almost daily that we would fail to introduce a catheter, he at last consented.

The bladder was opened by the usual technique and a small phosphatic stone removed. The collar-like protrusion of the prostate of the largest size was found to exist. After incising the prostate in four places the gland was removed by the fingers and the vesical mucous membrane remaining was cut off with scissors. As there was free bleeding a plug of iodoform-gauze, after Keyes' method, was attached to two threads, the one passing out through the urethra drawing the plug well into the prostatic urethra and tied over a similar plug at the external urethral orifice, and the other out through the supra-pubic opening. These remained for twenty-four hours, and were removed. The man showed every evidence of making a slow recovery until the ninth day, when fever with an unchecked diarrhœa set in, and he died on the eighteenth day after the operation. This patient was really worn out by his disease before the operation. His kidneys were seriously affected, mechanical obstruction to the passage of urine having ended in cystitis, ureteritis, and pyelitis.

Christopher Heath, in reporting an operation for stone by the high method, in which chronic cystitis existed, says that he applied to the lining membrane of the bladder a solution of silver nitrate, 20 grains to ℥j of water through a vulcanite speculum. This treatment almost immediately changed the alkaline and offensive urine to an acid and comparatively healthy secretion.

Now the question might be asked: Would it not be good surgery, in such advanced cases as this, for us only to make the supra-pubic incision and apply the solution of nitrate of silver to the lining membrane of the bladder and form a urinary fistula; then, when the patient has regained his strength and the cystitis has improved, to perform a second operation for removal of the prostatic growth? Under the circumstances would we not avoid making a fresh wound in a highly septic cavity and substitute a minor operation for a more serious one?

I have been induced to speak of this operation in order to popularize it, as I believe it is the simplest and best cutting operation for stone and the only operation for the removal of prostatic enlargement in two-thirds of the cases, as well as the only one by which tumors and ulcerations of the bladder can be properly treated.

Fehling, of Basle, has been elected Professor of Gynecology and Obstetrics at Halle in succession to Kaltenbach, recently deceased.

ORIGINAL LECTURE.

PIGMENTATION OF THE WHOLE SURFACE OF THE BODY, OCCURRING SUDDENLY OURING THE TREATMENT OF A CASE OF PSORIASIS; WARTY GROWTHS UPON THE PALMS AND SOLES, FOLLOWING THE INTERNAL USE OF ARSENIC.[1]

BY ALBERT E. CARRIER, M.D.,
OF DETROIT;
PROFESSOR OF DERMATOLOGY AND OF CLINICAL MEDICINE, DETROIT COLLEGE OF MEDICINE; DERMATOLOGIST TO HARPER HOSPITAL AND ST. MARY'S HOSPITAL.

THE case to which I wish to call your attention this morning illustrates three affections of the skin, two of which are of more than ordinary interest. Our patient is thirty-two years old, has the appearance of a man in pretty good health, is a carpenter by occupation, and has a good family history; one brother died at the age of twenty from a disease of the skin that, our patient tells us, had existed from the time he was six weeks old, and which covered the whole surface of the body with thick, white scales. When our patient was fourteen years old his scalp became affected with psoriasis, the lesions itching intensely; at sixteen he had gonorrhea, and has had a urethral discharge ever since. Various remedies were used for the scalp-disease, but without benefit until mercurial ointment was applied; this would keep the disease in check, but did not cure it; it was used for three years, when lesions of psoriasis developed on the body, and the mercury was stopped; six months later the man had an attack of rheumatism that confined him to his bed for nine months.

Three years before his attack of rheumatism he had a hard pimple on the dorsum of the penis that persisted for three weeks; at the same time the inguinal lymphatics were enlarged but not painful. A smooth white scar marks the site of the lesion of the penis. For his rheumatism he was sent to Mt. Clemens, Mich., and after taking the baths for six weeks (during which time he also took potassium iodid), his rheumatism and the cutaneous affection were both apparently cured. A short time after he stopped the baths the eruption reappeared on the body, and with it a chocolate color of the whole surface; so marked was this that he was taken for a mulatto, and on that account he was refused the rent of a house. The pigmentation gradually disappeared from the face, hands, and feet, but has continued upon the other portions of the body up to the present time. Viewing the patient from your seats his skin looks as though a mixture of pepper and salt had been thrown over it. There is no scaling except upon the dime-sized patches of psoriasis that are scattered over the belly, back, and on the inner surfaces of the arms. You will notice that where the psoriatic patches have disappeared their site appears very white in contrast with the pigmented skin; looking a little closer, we find that the discoloration has, all through it, white spots of normal colored skin, varying in size from a pinhead to a pea, and all circular in outline.

Anomalies in pigmentation are not uncommon; you see them in the yellow-brown spots of lentigo upon the face and hands, or in the larger and browner patches, the moth-patches, found on the face, breasts, and abdomen of pregnant women, or in those suffering some pathologic condition of the uterus or its appendages, or in severe cases of pruritus, due to scratching or following a prolonged congestion of the skin. Again, they occur as the remains of the lesions of certain skin-diseases, such as prurigo and syphilis. In most of these instances the pigmentation will disappear in a short time, and the surface covered is not very large. Pigmentation also occurs in some cases of chronic malarial toxemia and in abdominal tuberculosis.

Another cause is found in the local application of certain medicines, or the internal administration of drugs, such as silver nitrate, which in certain individuals produces a chocolate color of the skin that is permanent; arsenic is also followed in some persons by a staining of the skin. Discolorations also occur as a result of the absorption of the coloring-matter of some of the secretions, an example of which is jaundice, as a result of obstruction or of catarrh of the gall-ducts.

Two other diseases that are followed by pigmentation must be noticed, viz., syphilis and disease of the supra-renal capsules, known as Addison's disease.

In Addison's disease the bronze color is not always present; but when it is we find it most marked upon the face and hands, and it is also found upon the mucous surfaces. The disease is gradual in its onset and accompanied by symptoms of severe constitutional disturbance, as manifested by the asthenia, the weak pulse, the gastric symptoms, palpitation on slight exertion, and syncope—symptoms that are referable to the sympathetic nervous system—and the color gradually becomes darker, and is permanent. The disease tends to a fatal issue, death occurring within a few years.

The syphilitic coloring that I refer to is not that which follows the disappearance of a syphilid, but is itself a syphilid—the pigmented syphilid. This is a rather uncommon occurrence, and is seen oftener in men than in women; it is usually seated on the sides of the neck, but may cover larger surfaces, and misses the face and hands; it appears during the first few months of the disease, lasts for several months, and is very rebellious to treatment; it may also occur at a later period of the disease. The patches are circular in outline, yellow-brown in color, and do not scale.

The interesting facts connected with this case are: first, the sudden appearance of the staining, the whole surface of the body being covered in a few days; second, the length of time that it has lasted, now over eight years; and third, the large surface covered.

From the history of the case and the appearance of the patient we are not warranted in ascribing this pigmentation to Addison's disease; the man is in apparently good health; he has none of the constitutional symptoms of disease of the supra-renal capsules; and, more than all, he is alive; the chances being that, with Addison's disease, he would have died several years ago. Regarding abdominal tuberculosis as a probable cause, we are confronted with the same absence of characteristic symptoms; there has been no tenderness of the belly, no enlargement, no anemia, no debility; the family history shows no inherited tendency to the

[1] Clinical lecture delivered at St. Mary's Hospital.

affection, and the pigmentation of this disease is not so pronounced as in our patient, nor so generally distributed.

I do not think that it is the pigmentary syphilid, as it did not occur for over four years after he had the hard pimple on his penis, and he has never had any other manifestation of that disease, neither loss of hair, sore-throat, pains in the bones, eruptions of any kind excepting the psoriatic, and the lesion of the penis may only have been a psoriatic lesion.

Excluding all these diseases from a causative relation to the discoloration, we would probably have to call it a trophoneurosis, which in many instances is as clear as to say that a patient has liver-complaint.

Now examine the patient's hands and you find that the whole palmar surface is thickly studded with warty growths, from the size of a pinhead to that of a pea, hard, deep-seated, and painful; several of these lesions are on the back of the last phalanges also. The soles are the seat of similar growths. This condition has lasted for over two years, and in order to walk or work at his trade with any comfort, he is obliged to pare the growths with a razor. Two years and a half ago our patient began the use of Fowler's solution, which, in doses of from 5 to 10 drops, seemed to keep the disease in abeyance; he has continued to take the medicine until the present time. Six months after he began the use of arsenic the affection of the soles and palms began, and has remained until now.

Here, then, I think, is our explanation of the causation of the pigmentation and of the warty condition of palms and soles. He had probably taken arsenic before he ever went to Mt. Clemens, and the coloring was the result of the administration of that drug; he had also taken it for a long time, for the reason that the pigmentation is general, instead of its occupying the sites of old psoriatic lesions, which is the case when the color occurs early in the treatment. I am at a loss to account for its sudden appearance. I find, however, that this man's skin is very sensitive, that he is obliged to wear the finest underwear, that a slight injury to the skin is followed by a pigment-deposit; it may be that the constant bathing in the irritating waters of Mt. Clemens for so long a time was the determining cause.

Our patient seeks relief; he wants to get rid of his psoriasis, of his abnormal color, and of the affection of the palms and soles.

In the treatment of psoriasis arsenic stands at the head of all internal remedies; it probably cures (so far as cures can be expected, for all cases tend to relapse) more cases of the disease than all other drugs used, but it is contra-indicated in this case even if we had no pigmentation or warty growths. The contra-indicating symptom in the case is the pruritus; I never give the drug in this disease when itching is intense. I think we will give him increasing doses of potassium iodid, which has been highly spoken of in some cases of the disease. Local treatment, so valuable in all cases, we will have to dispense with on account of the liability of its causing increase of pigmentation. Psoriatic patients usually have the appearance of being in perfect health; in fact, many are far above the average. Proper diet, however, is important; our patient says he lives mostly on lean meat, coffee, very little starchy, and no oily food, if he can avoid it. He suffers more from cold than the ordinary person, and I think he needs what he omits from his food—fat and starch; we will give him vegetables to furnish the starch, and, if he will not take fat as food, oil as medicine. The gleet must be cured. Whatever drug or treatment we decide upon in a given case should not be discontinued until it has been given for a considerable length of time, even if at first the disease seems aggravated. With patience on the part of the patient, with careful scrutiny and removal of trivial symptoms, and proper medication, the lesions of psoriasis can be made to disappear within from one to three months.

Let us now consider the pigmentation. Is there any means by which we can hope to relieve him of this disfigurement? The color of the skin in the white race is due to the deposit of pigment-granules in the lower layers of the rete cells; the amount varies as the individual is light-colored or dark-colored, and when abnormal pigmentation occurs, all the cells of the epidermis may be stained; the pigment itself is normal, only increased in amount. In argyria the silver is deposited in minute particles in the derma, and the same is true of the substances used in tattooing. It is interesting to notice the tolerance of the skin to the presence of a foreign body, these substances remaining throughout the whole life of the individual without causing the slightest inconvenience. The source of the normal pigment is the blood, the lower layer of epidermic cells selecting and depositing the granules, but I think that these same cells are manufacturers as well as selectors and that from their own protoplasm they may, under certain influences, produce the pigment. The arsenic-staining is due to the stimulation of rete cells by the drug, and not to a deposit of the metal in the derma. The specific treatment of hyper-pigmentation is eminently unsatisfactory, and before beginning any treatment we must be positive that the process is at a standstill. Those dyschromæ which are symptomatic of disease of the liver and uterus may disappear when these organs are restored to their normal condition, and to this end our therapy is directed. The specific treatment consists of the use of local applications that will hasten the reproduction of epidermis, the new and unpigmented taking the place of the old pigmented epidermis. Epidermis is easy enough of removal by such drugs as croton oil, mustard, and cantharides, but these are unavailable because their use is followed by an increased deposit of pigment. Nitric acid, hydrochloric acid, acetic acid, corrosive sublimate, and hydrogen dioxid will remove the epidermis and not be followed by increase of pigment. If time is no object borax, sulfur, or the alkaline soaps may be used, the slow process, I think, giving the best result. By the rapid process we aim to form a blister over the stain quickly, and then subdue the irritation as quickly as possible. In the case of the man before us there are reasons why this treatment would not be best: first, because of the large surface involved; second, it is upon parts of the body that are covered; and third, the process is not at a standstill, as we find that new areas of pigment are appearing while old ones are disappearing, and any effort that we might make is likely to be followed by an increase rather than by a decrease of pigment.

Let us now consider the affection of the palms and soles. Here we find the whole surface thickly studded with these dome-shaped epidermic lesions; for the most part each lesion preserves its identity, although so numerous are they that their borders touch all around, and so fast are they developed that he is obliged to pare them off at least twice a week; the condition interferes with his work, and is a matter of grave import to him. Ordinary callosities, or those due to occupation, offer some chance of being bettered by treatment or by giving up the occupation; but in this case neither rest nor any local application that has been used has been of any benefit. Internally in these cases we rely upon arsenic; but here we are again handicapped, for we believe the condition was caused by the use of this drug, and we have stopped its use. Locally we will have the parts pared down close, and then apply a plaster of salicylic acid (15 per cent.) for three days, when, on its removal, we will be able to peel off the epidermis; an alkaline ointment should then be bound to the surface for twenty-four hours, and on its removal a simple fat applied. The process will have to be repeated as often as the growths re-form. I shall hardly expect to get a permanent cure, relief being the best we can hope for. The case is an interesting one, and has shown us that serious untoward effects sometimes follow the giving of arsenic. The lesson it teaches is that it is better to treat first with other drugs those affections of the skin in which arsenic seems indicated, reserving for the arsenic those that resist all other medication.

CLINICAL MEMORANDA.

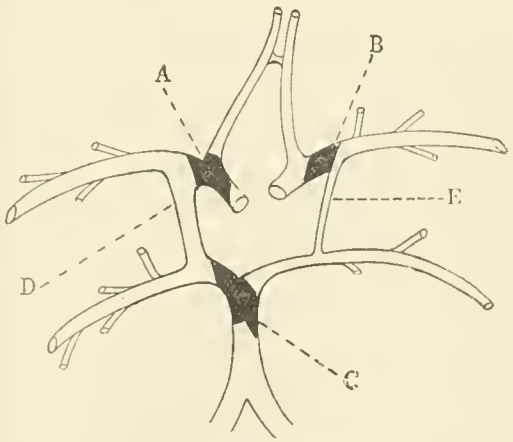
MULTIPLE THROMBOSIS OF THE CIRCLE OF WILLIS.

By JOSEPH LEIDY, M.D.,
of Philadelphia;
Physician to the Out-Patient Department of the Pennsylvania Hospital; Assistant Physician to the Hospital for Epileptics.

Cases of multiple thrombosis of the cerebral arteries, producing a group of symptoms similar to those presented by the case reported by Dr. J. T. Eskridge in The Medical News of January 6, 1894, are so unusual that I may be pardoned for occupying a brief space to refer to a similar case, including a report of the autopsy, presenting almost an exact duplicate of the clinical picture of the case of Dr. Eskridge.

At the meeting of the American Neurological Society, held in June, 1890, I had the honor to present an interesting pathologic specimen of "Multiple thrombosis of the circle of Willis, in connection with a series of anomalies and asymmetries found in thirty-five specimens of the circle of Willis," believing the explanation of frequent evanescent palsies, embolic or thrombotic, to reside in either an anomalous or asymmetric condition of these arteries, which is far more frequent than is generally supposed. The pathologic specimen presented proved this to be the fact in explanation of an attack in a case which I reported to the Pathological Society of Philadelphia in November of the same year.

The patient, a colored man, thirty years of age, married, addicted to the use of alcohol and tobacco to excess, with a syphilitic history, was admitted to the medical wards of the Pennsylvania Hospital May 10, 1890. He had been bled at the nape of the neck at intervals of six months for three years previously for the relief of occipital headaches, and it was his intention to have been cupped on the day previous to his admission to the hospital. While driving his cart he noticed a loss of power in the right leg and arm, his tongue felt thick, articulation was difficult, and he would have fallen had he not been caught by his companion who was driving with him. Twelve hours after he was brought to the hospital he had incontinence of urine added to the foregoing group of symptoms; he was dazed, but conscious; his tongue was protruded toward the paralyzed side. His condition improved during the following five days, with some return of power in the right arm, and considerable improvement of speech. On the sixth day there was some loss of power noted in the left leg, and in the course of twenty-four hours the whole of the left side of the body was involved. He became unconscious on the following day, with also secondary loss of power in the right arm and with involvement of the sphincters. Death supervened in forty-eight hours. The clinical picture presented by this case strikingly portrays the group of symptoms and the course in Dr. Eskridge's case. The pathologic specimen is now preserved in the Mütter Museum of the College of Physicians for reference.



A. Thrombus in left middle cerebral artery.
B. Thrombus in right middle cerebral artery.
C. Thrombus in basilar artery.
D. Large left posterior communicating artery.
E. Unusually small right posterior communicating artery.

I believe the amelioration of the symptoms following the first seizure to have been due, first, to a cessation of the pathologic process through heroic antisyphilitic treatment; and secondly, to the anomalous and asymmetric condition of the circle of Willis, which afforded a partial collateral circulation to supply the left hemisphere through the outer distribution of the middle cerebral artery by way of an enormously large left posterior communicating artery. I append a rough sketch of the specimen.

The diagnosis of thrombosis of the cerebral arteries was made ante-mortem, and confirmed subsequently by the characteristic lesions found at the autopsy.

This description, in conjunction with the case of Dr. Eskridge, makes the picture both clinically and pathologically one of extreme interest.

233 SOUTH THIRTEENTH STREET.

THREE CASES OF PARTIAL PARALYSIS OF THE OCULAR MUSCLES FROM INJURY TO THE HEAD.

BY VITO L. RAIA, M.D.,
OF PROVIDENCE, R. I.

1. PARALYSIS OF THE EXTERNAL RECTUS OF THE RIGHT EYE.—A man, aged sixty-three years, was struck on the left parietal region by a board, sustaining a contused wound of the scalp. He remained unconscious for several hours and afterward complained of headache and dizziness. Three weeks after the accident the patient began to see double. When examined, vision was normal, abduction of the right eye abolished, movements in all other directions normal. The double images (homonymous diplopia) were fused into one at 20 feet with a prism 26°, base outward.

2. PARALYSIS OF THE SUPERIOR OBLIQUE OF THE LEFT EYE.—A man, aged forty-five years, fell and sustained a contused wound of the upper part of the right temple. Three days after the accident the patient began to notice a disturbance of vision. At the site of the injury there was a scar one inch long, in a horizontal direction. Vision of both eyes was normal. The patient kept his head bent toward the right side, with chin depressed and lids wide open; diplopia was very embarrassing. In testing the latter with a candle, the left (or false) image, which belonged to the left eye, was downward, with the upper extremity inclined toward the median line, and closer to the body of the patient than that of the right one. Diplopia was present only when the object was brought in the lower common field of vision.

3. PARALYSIS OF THE INTERNAL RECTUS OF THE RIGHT EYE.—A boy, aged nine years, was struck on the upper part of the temporal region of the right side by a can of milk, thrown from a train. He remained unconscious for two days. Four weeks after the accident the patient began to complain as regards his eyes. When I saw the boy there was a scar about two inches long and three-quarters of an inch wide transversely, situated at the upper and posterior part of the temporal region. The surface of the scar was very irregular and considerably lower than that of the skull, due evidently to fracture of the latter, with depression of the fragments. Vision was normal, mental faculties perfect, movements of convergence of the right eye weakened. The patient had diplopia (crossed).

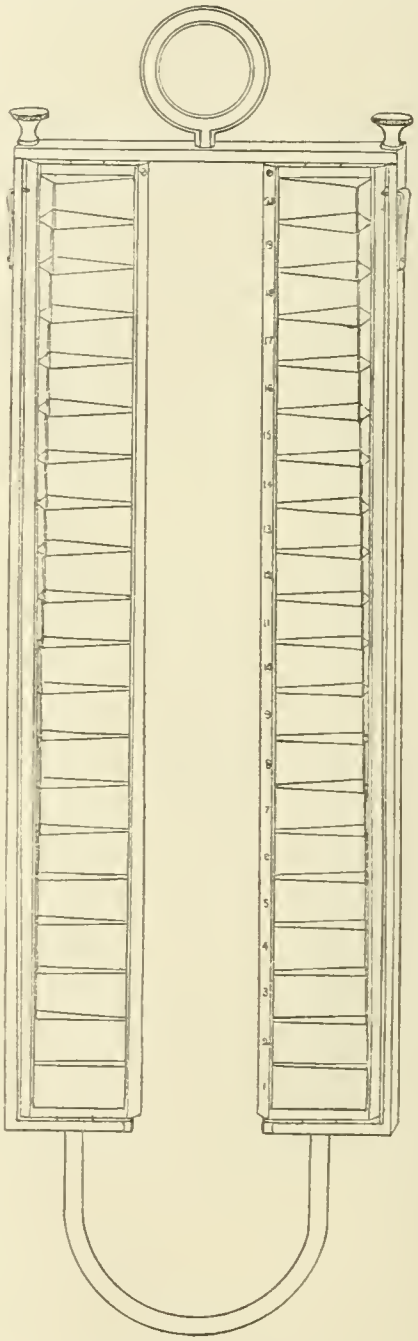
These cases came under my observation at the same time and show the following peculiarities: 1. In the first two cases the injury was on one side of the head, while the ocular paralysis affected the opposite eye. 2. In the last case, while the compression seemed to be exerted upon the brain, the permanent injury was limited to a branch of the oculo-motor nerve. 3. The paralysis of the ocular muscles came on some days after the accident (three weeks in the first, four weeks in the last, and two days in the second case).

NEW DEVICE.

AN ARRANGEMENT OF PRISMS FOR TESTING ADDUCTION, ABDUCTION, EXOPHORIA, AND ESOPHORIA.

BY GEORGE M. GOULD, A.M., M.D.,
OF PHILADELPHIA.

IN testing for exophoria and esophoria, and in measuring the power of adduction or of abduction, I have found



the common methods in use both time-wasting and vexatious, and have suggested to Messrs. Wall & Ochs, opti-

cians, 1702 Chestnut Street, Philadelphia, that a double series, "battery," or "pile" of prisms would be of service. The illustration given herewith is the result of our mutual efforts, and after thoroughly testing the instrument I commend it as, mechanically, beautifully made, and, scientifically, admirably effective and convenient. The prisms begin with 1° lenses upon each side, and increase by integers to 20°, so that with 2° steps one may measure all degrees of adduction or of abduction from 2° to 40°. The open central space permits the lenses to be brought close to the eyes without any interference with the patient's nose. The larger handle below allows the first tests to be made with the lowest-power prisms, likewise without striking the nose; and the lowest-power prisms are placed below in order that in testing from low powers to higher powers, the patient's breath may not cloud the lenses to be used next in order. To measure adduction each "battery" is placed "bases out;" to measure abduction, each is revolved so that the bases are "in." To test exophoria and esophoria, the same methods are pursued, the Maddox-rod (*red*) being first placed before one eye in the trial-frame. Each battery is revolved at pleasure, being fixed by a pivot-mechanism below and above, and temporarily held in the position desired by clutches at the sides opposite the 20° prisms. By this mechanism the four tests desired may be made with great celerity and ease. The instrument may also be used for short periods of exercise in adduction or abduction. The illustration is one-half the actual size.

MEDICAL PROGRESS.

Compression of the Spinal Cord by Echinococci.—Friedeberg (*Centralbl. f. klin. Medicin*, 1893, No. 51, p. 1057) has reported the case of a man, thirty-one years old, who for a period of more than three years had suffered with pain in the right thigh, of varying intensity, and shooting in the course of the sciatic nerve. For a short time there had been some incontinence of urine, particularly as a result of violent coughing. There was some sensitiveness on pressure in the hypogastrium and in the course of the right sciatic nerve. The knee-jerks were normal and there was no derangement of common sensibility. An attack of looseness of the bowels was attended with the evacuation of a number of segments of tenia solium, and a course of filix mas was prescribed. Some time later pain in the region of the anus was complained of, and on inspection the skin in this region was found reddened and the tissues infiltrated, while a small blind fistula passed for a short distance by the side of the rectum. In due time the periproctitic abscess healed. The pain in the right thigh persisted, and to it became added numbness of the foot, while the gait became staggering and the temperature was slightly elevated. As time went on, the knee-jerks became exaggerated and ankle-clonus appeared. Pain was also complained of on pressure in the lower dorsal and upper lumbar regions. Finally the loss of power in the lower extremities became complete, marked impairment of sensibility developed, and control of the bowel was lost. Electric irritability was lost, bedsores and other evidences of trophic disturbance appeared, and several fluctuating tumors became evident in the abdomen. Death took place amid the signs of respiratory failure. Upon post-mortem examination the sacrum was found to be destroyed and replaced by a gelatinous collection, in the midst of which numerous small vesicles could be seen. Gelatinous masses and vesicles extended in the length of the vertebral canal to the level of the second dorsal vertebra, compressing the cord, without having penetrated the dura mater. In the region of the last lumbar vertebra the cord was compressed to a delicate band. Small cavities were found in either lung and a mother-cyst with numerous daughter-cysts in the right iliac fossa. In the daughter-cysts scolices and hooklets were found. The right ureter and kidney presented the changes that follow obstruction to the flow of urine.

Pulsation of the Larynx due to Arterial Anomalies.—At a recent meeting of the Berlin Society for Internal Medicine, Litten (*Deutsche medicinische Wochenschrift*, 1893, No. 47, p. 1224) reported the case of a nervous woman, fifty years old, who complained of precordial distress, palpitation of the heart, manifestations of tachycardia, and an uncomfortable sensation in the throat, together with marked beating of the vessels of the neck and pulsation of the larynx. With the cardiac systole the larynx was elevated and displaced to the left. The pulsation could also be observed in the whole course of the trachea. Physical examination failed to disclose the signs of hypertrophy of the heart, valvular disease, or aneurism of the arch of the aorta. The vessels that arose from the arch, however, pulsated strongly and were evidently greatly dilated. It was concluded that there must be an aneurism of one of the vessels arising from the carotid artery to supply the thyroid gland, either the laryngeal or the thyroid, although the evidence was not demonstrative. At a later period it was thought that a diastolic murmur could be heard over the sternum. The woman finally died, and upon post-mortem examination it was found that four large vessels took their origin from the arch of the aorta, the one arising between the left carotid and the left subclavian representing a thyroidea ima. This anomalous vessel was as large as a normal radial, and ascended along the middle line of the trachea to the level of the second ring, where it divided into three branches, which broke up into many smaller ramifications upon the surface of the thyroid gland. All of the vessels that arose from the arch of the aorta were greatly dilated, while the innominate was additionally conspicuously elongated. The intima of these vessels presented areas of fatty degeneration, but no evidences of pronounced atheroma, such as ulceration or calcification.

Paretic Dementia at Puberty.—Bristowe (*British Medical Journal*, No. 1716, p. 1099) has reported the case of a boy, thirteen years old, who two or three years before had been knocked down by a horse and trap, which went over him, the shaft striking him on the back of the head. The child was stunned and remained unconscious for about three hours. Before the accident he was bright and intelligent, but afterward was never the same. Intellectual ability gradually declined. Fourteen months before coming under observation the boy had some kind of seizure in which he lost power upon the left side of the body. The weakness remained and the

child gradually grew worse, and finally became unmanageable. He shouted and screamed without cause, tried to run away, and became dirty in his habits and violent in his conduct. The pupils were equal and sluggish, though later the left was larger than the right. The knee-jerks were at first greatly exaggerated, but later were lost; ankle-clonus could not be elicited. The gait was spastic; the tongue was tremulous, but protruded straight. Speech was hesitating. The hands were held before the face all day and were rubbed, while unintelligible sounds were uttered. While under observation the boy had a convulsive seizure, apparently attended with loss of consciousness. Twitching of the right eye and hand were first noticed, and later the muscles of the right side of the face were involved. After the attack the right leg was found to be weak. Emaciation progressively increased, so that it became necessary to keep the child in bed. He had two other seizures, one involving the left side, the other the right. As time went on the boy passed a purely vegetative existence, exercising no control over the sphincters. Though he took food voraciously the emaciation persisted. There was at no time vomiting or optic neuritis.

Differentiation of B. Coli Commune from B. Typhosus.—FREMLIN (*Archiv f. Hygiene*, vol. xix, fasc. 3), as part of the result of an extended study of B. coli commune from various animals, gives the following summary of the differences between that species and B. typhosus:

1. The motion of B. typhosus is more active and more extensive. 2. B. typhosus shows a much greater tendency to form threads, as two or more individuals are often seen joined, and six or ten in line are not unusual; with the other species such a thread-like form is almost unknown. 3. The growth of B. typhosus on gelatin is distinctly slower; colonies three days old are not further advanced than two-days-old colonies of B. coli commune. This difference is also observed on agar-plates and in stab-cultures. 4. Colonies of B. typhosus are almost invisible on potato, while B. coli commune forms distinct broad orange streaks. 5. B. typhosus has no fermenting action, while the other bacillus possesses well-marked powers in this respect. 6. B. typhosus does not curdle milk, while B. coli commune does. 7. B. typhosus has many flagella. Preparations showing these clearly may be obtained without difficulty from cultures a week old. In this we note a marked difference from B. coli commune, as with it preparations showing flagella are very difficult of demonstration, even under favorable conditions. 8. B. typhosus does not give the indin (indol) reaction with potassium nitrite, while B. coli commune does.

The Etiology of Melæna Neonatorum.—GARTNER (*Archiv f. Gynäkologie*, B. xlv, H. 2, p. 272) has reported two cases of melæna neonatorum, in which examination of the intestinal contents and evacuations, as well as the blood from the heart and the spleen, and the tissues of the spleen, liver, and intestine, disclosed the presence of a short bacillus, with active movement and discernible flagella, multiplying the fission and giving rise to the production of gas. The organism was cultivable upon the ordinary media, and stained readily with anilin colors. Inoculation of young animals, especially dogs, gave rise to the production of a condition comparable to melæna as seen in newborn children, and in the blood and organs of these animals were found organisms the same as those inoculated. The opinion is expressed that the organism found is the causative agent of the morbid condition with which it is associated, and further, that the umbilicus constitutes the portal of entry, as in most, if not all, recent cases, the evidences of peritonitis are to be found.

Tincture of cannabis indica . gtt. xv.
Glycerin . . . . . f℥iv.
Distilled water . . . ad f℥ijss.—M.
S.—A dessertspoonful p. r. n.

℞.—Butyl-chloral hydrate . . . gr. xvi.
Extract of cannabis indica . . gr. iv.
Make into 16 capsules. Take 2 at once, and 1 every hour or two hours until relief ensues.
Nouv. Rem.; Journ. de Méd. de Paris, No. 49.

For Epilepsy.—

℞.—Potassii bromidi . . . . ℥iv.
Tincturæ belladonnæ . . . f℥iij.
Infusi gentianæ compositus . ad f℥viij.—M.
S.—A tablespoonful thrice daily.

℞.—Camphoræ monobromat. . . gr. xlviij.
Ext. gentianæ . . . . q. s.
Ft. massæ et div. in. pil. no. xij.
S.—One at bedtime.
BLACK, *British Medical Journal*, No. 1723, p. 13.

For Prostatitis.

℞.—Ichthyol . . . . . gr. vijss.
Ext. belladonnæ . . . gr. ijss.
Olei theobromæ . . . ℥iv.—M.
Ft. suppositoriæ no. x. S.—Introduce one into the bowel once or twice daily.
ULLMANN, *Wien. med. Zeitg.*, No. 29; *Les Nouv. Rem.*, No. 23.

For Pruritus Vulvæ.—

℞.—Hydrarg. chlorid. corrosiv. . . gr. j.
Aluminis . . . . . gr. xx.
Pulv. amyli . . . . . ℥jss.
Aquæ menth. piper. . . ad f℥vj.—M.
Ft. lotio.
S.—Apply topically. *Practitioner*, No. 306.

For Tinea Tricophytina.—

℞.—Sodii hyposulphitis . . . ℥j.
Spts. rectificat. . . . . ℥iv.
Aquæ . . . . . ad f℥viij.—M.
Ft. lotio.
S.—To be applied to the affected parts after they have been thoroughly washed with a brush and soap and water. *Practitioner*, No. 306.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, FEBRUARY 3, 1894.

TO PREVENT THE SPREAD OF TUBERCULOSIS.

IT will surely not be gainsaid that much practical benefit has already accrued through the young science of bacteriology. Though all may not admit the value of protective inoculations, there can be none that will deny the great advances that have been made in sanitary science in the last decade as a direct outcome of the results of bacteriologic research. Not only have we thus been furnished with a rational explanation for the employment of hitherto empiric methods of sanitation and hygiene, but there have likewise resulted an increased saving of life and the avoidance of immeasurable disease. As in all questions, so in this, there have been extremes of view. On the one hand there are those for whom it is not too much to claim almost unlimited possibilities for bacteriology; while on the other hand there are not wanting others who with equal ardor deny the new science everything. Between these two extremes is the judicial mean, including those upon whom falls the important but not agreeable task of harmonizing conflicting opinions and of neutralizing the antagonizing influences of unrestrained zeal and torpid conservatism.

We have now learned enough of schizomycetes to know that they are almost omnipresent; but we have further learned that their mere presence does not of itself constitute disease. In the development of the so-called specific disease-processes something is needed in addition to the presence of the micro-organism that acts as the exciting cause—and this is the predisposition, *i. e.*, to use a favorite simile, the soil must be suitable for the implantation and fertilization of the seed; else this will not thrive. Now if this knowledge has any significance and is to be put into practical application, it means that for prophylactic purposes the greatest stress must be laid upon and the greatest attention paid to both individual and civic hygiene; that is, the resisting power of the individual must be increased, his susceptibility to disease diminished, and the causative agency attenuated or eradicated. Granting, then, the potency of these several factors in the causation of disease, it must be perfectly obvious that the liability to disease will be diminished if the influence of any or all is removed.

At the present time quite an active agitation is going on in various parts of the United States as to the wisdom of including tuberculosis, and particularly pulmonary tuberculosis, among the diseases professional cognizance of which should be reported to some central health-authority, with the object of employing such hygienic and sanitary measures as the circumstances seem to indicate or warrant for restraining the spread of a disease for the prevention of which it is known that so much can be done. Legislation to this effect has already been enacted in the State of Michigan, where it is obligatory upon physicians to report to the Board of Health cases of tuberculosis under their professional care, and in the city of New York the Board of Health also requires notification of cases of tuberculosis. Such a course of action has, besides, the indorsement of the French Congress of Tuberculosis, the American Public Health Association, and the Section of Hygiene of the Pan-American Medical Congress. Missionary work is being done in this direction by the French League for the Prevention of Tuberculosis, and by the Philadelphia Society for the Prevention of Tuberculosis.

As is the case with every scientific advance, so the proposition of registration in tuberculosis has encountered not a little opposition. Among other objections it is suggested that the unfortunate victims of the disease would thus be branded with an irremovable stigma, that they would be shunned by their fellows, that the doors of society would be closed to them, that their personal liberty would be

interfered with, and that other more or less irksome restrictive measures would be adopted. Of this radical extreme there need be little fear, the difficulty itself arousing an adequate and sufficient sense of such danger. Over-zeal seems less probable than under-zeal. Most likely in actual outworking only such measures would be enforced as would tend to result in improving the condition of the sick and saving the well from infection, without undue trespass on liberty and without any real hardship to the sick or to his friends. In exactly what these measures would consist, if registration became general, would be a subject for future mature deliberation. Nor is it unlikely that the medical profession would be ignored in the framing of the rules governing the entire course of procedure.

The situation appears to be simply this: It is generally admitted that the tuberculous patient constitutes the focus whence transmission of the disease occurs. This most commonly takes place through the intermediation of the expectorated matters, which being indiscriminately disposed of, become dry, are ground to powder, and in the form of dust are carried by currents of air to find lodgment, especially in the respiratory passages of the well, some of whom are predisposed by heredity or by unfavorable hygienic surroundings to the infection; or they fall upon exposed articles of food or drink, and in this manner gain access to the gastro-intestinal tract. It is the almost universal consensus of opinion that if the sputum were in the first place properly disposed of, the danger would at once be greatly diminished. In the failure of this it becomes necessary as far as possible to sterilize the contaminated surroundings of the patient, including the bed-clothing and the body-clothing, the furniture, the walls and floors of the living-rooms and the like. Under existing circumstances the conscientious physician will in the individual case advise that such steps be taken, but he has no means of insuring their carrying out, and, besides, there remain a considerable number of cases that do not come under the physician's immediate care, and that require attention directly from the health authorities. It thus comes about that what is everybody's business is nobody's business—and that is the present status of affairs.

It is obviously the poor, the ignorant, and the indifferent that suffer most and likewise constitute the greatest menace to others in this connection. Will anyone undertake to say that among these, suitable precautions are taken in any considerable proportion of cases? Now if there were a central health-authority (such as a Board of Health) to which notification should be made of houses in which tuberculous persons reside, such a body could in a given case direct or conduct a proper sanitary investigation and could determine upon the line of action to be taken. It could, for instance, recommend to the house-owner or the house-occupants, as the circumstances seemed to demand, the carrying out of certain measures; and in case these were not adopted the body could then have authority to undertake the necessary procedures on its own account. If, as is the case, improperly constructed buildings may be condemned, house-drainage must be subjected to official scrutiny, and nuisances of one kind or another may be suppressed, surely it does not seem unreasonable that the State or the municipality should have the power to declare as a menace to health and life certain houses or quarters that are recognized to be centers of disease-infection. Nor should such authority be withheld by reason of fear that a perfect system of sanitation does not appear immediately feasible, or because everything that it is thought should be done does not seem at once capable of performance. As experience accumulates, old methods would be improved and new methods devised. It does not seem likely that a body thus empowered would attempt the impossible.

In addition to the functions of caring for the hygienic and sanitary surroundings of tuberculous patients unable or unwilling from poverty, ignorance, or indifference to exercise such care, such a body could also see that both well and sick were instructed by means of tracts, and perhaps also by means of popular lectures, as to the nature of tuberculosis, its dangers, its mode of transmission, and the best means of preventing its spread and staying its advance.

To sum up briefly, our own position is practically this:

Tuberculosis is a disease that is transmissible from the sick to the well. Its perpetuation and its transmission depend upon a condition of lowered vitality (sometimes hereditary, but more commonly the result of unfavorable hygienic conditions and habits), in conjunction with a failure to sterilize the sputum by some approved means and the contamination of the surroundings of the tuberculous. These

conditions are to be best remedied through the intelligent action of a properly authorized and organized central body, together with the hearty coöperation of the medical profession, both individually and collectively. With this end in view, registration of houses in which tuberculous persons reside (in case of death notification is now almost universally made through the usual channels) would tend to insure a proper carrying out of suitable sanitary measures, and the instruction of such persons and their friends as to the best means of preventing the further spread of the disease, and also as to the best mode of life for the sick.

EDITORIAL COMMENTS.

Associations for the Relief of Widows and Children of Deceased Medical Men.—We have on a previous occasion spoken of the wisdom and philanthropy of organizations for the relief of indigent widows and children of deceased medical men, commending their formation everywhere, and urging all physicians to enroll themselves as contributing members. The excellent work done by existing associations must constitute the strongest argument for their maintenance and the extension of their usefulness. From a recent report of the Board of Managers of the N. Y. Society for the Relief of Widows and Orphans of Medical Men, we learn that during the year 1893 eleven widows and three children of deceased members were relieved; $6610.30 were added to the permanent fund, which has reached the respectable proportions of $189,157.06. The membership of the Society numbers 143, and the expenses for the year were but $180.30. The number of benefactors is 55, most of whom have contributed $150 each. The largest gift is one of $20,000, by the late Dr. Alonzo Clark. In addition to this Society there exists in New York also a Physicians' Mutual Aid Association, which provides for the payment of $1000 to the representatives of a deceased member, whose fees during life would have been from $15 to $20. Our own Mutual Aid Association of the Philadelphia County Medical Society is likewise doing excellent work, its usefulness, however, being restricted by the smallness of its permanent fund. As the Association is not so much intended for mutual aid as for the relief of indigent widows and children of deceased medical men, a change in name to Benevolent Fund of the Philadelphia County Medical Society is properly contemplated. As one of the speakers said, at the recent annual meeting of the Association, it would be desirable to have the benefactions of the Society also extended to the families of other medical men than those that have been members. Such a noble end is only to be attained by the creation of a large permanent fund. It thus becomes the duty of every medical man to enroll himself as a member of his local Aid Association, to contribute as largely to its funds as his means will allow, and to exert his influence among his clients and friends to induce them to contribute during life, and bequeath at death, generously, to so worthy and humanitarian a cause.

To Abolish the Office of Coroner.—An active movement is on foot in the city of New York to correct the abuses and inadequacies of the office of Coroner by abolishing the office or so modifying existing legislation as to eradicate the evils of the present system. A memorial has been prepared by a duly authorized committee of the Medico-Legal Society of the State of New York and presented to the Legislature asking for the desired reform. The recommendations proposed are:

The creation of a new officer to be styled "Medical Examiner" (as in Massachusetts and Connecticut), or "County Physician" (as in New Jersey), who shall be authorized to conduct inquests or examinations in all cases in which death has occurred by violence, or in which there is reason to suspect that death is due to other than natural causes. The duties of this officer should consist in the conduct of all autopsies and the decision of all questions on the medical side of the inquiry (without a jury) before a competent court or before the Coroner as a judicial officer, if retained after the plan adopted in Connecticut.

This medical examiner should be appointed by the county judges of each county, except in New York, where the appointment is to be made by the Chief Justice of the Court of Common Pleas. Only physicians skilled in their profession, of at least five years' practice, are to be eligible to such appointment, and, so far as possible, without reference to partisan or political considerations.

Only persons learned in the law shall be eligible to the office of Coroner, and if the inquiry is conducted before the Coroner he shall have charge, judicially, of all legal questions, and the hearing, inquest, and proceedings shall be the same as if before the police magistrates in the city of New York or other cities of over 100,000 inhabitants, and before justices of the peace in all counties of the State, except in New York and Kings counties.

The movement has our warmest indorsement and our heartiest wishes for its entire success. We could then look forward to the possibility of a similar much-needed reform in the State of Pennsylvania.

Liability of Railroad Corporations for Negligence of Physicians.—Whether or not it is within the corporate powers of a railroad company, under any circumstances, to oblige itself to the rendition of medical or surgical aid to its sick or injured employés, by assuming it as a duty or otherwise, or to become liable for any negligence of any such surgeon acting in the line of his profession, the Supreme Court of Florida says is a *quære*. If it can become so liable, it holds that its whole duty in that respect will have been performed when it employs a person of ordinary competence and skill in that profession; and that, having done so, it cannot be held liable for the carelessness or negligence of such surgeon in the performance of his duties as such. This was brought out in a recent case in which an injured employé undertook to fasten liability upon a railroad company on a charge that a surgeon who was employed by said company to render medical and surgical aid to injured employés did, in the exercise of his duty as such physician and surgeon, set his injured arm in such an unskilled and negligent manner as to render it ill-shaped, and forever useless to him in the

performance of any manual labor. There was no allegation or proof that the physician and surgeon so alleged to have been employed by the railroad company was not competent and skilled in the line of his profession; and, in the absence of such allegation and the proof to sustain it, the court said that the railroad company was not liable for any negligent exercise by such surgeon of his profession in the treatment of the employé complaining. Even though it should be admitted to be within the corporate powers of such a company to obligate itself to the rendition of medical and surgical aid to its sick or injured employés, by assuming it as a duty or otherwise, or to become liable under any circumstances for any negligence of any such surgeon acting in the line of his profession, still it would seem to be well settled that it will have performed its entire duty in that respect when it employs a person of ordinary competence and skill in that profession; and that, having done so, it cannot be held liable for the carelessness or negligence of such surgeon in the performance of his duty as such.

Mrs. Ernest Hart, the wife of the editor of the *British Medical Journal*, has during the past year become personally known to thousands of Americans, and the knowledge of her work to millions. In carrying to the Irish poor the means and methods of self-help this most remarkable woman has done a work that is good beyond estimation and compare, and has done it with a self-sacrifice that even those who know her most intimately can but barely guess. What the history of her life would be was well suggested by her refusal, as a girl, to wear fine or expensive dresses to church, and as a young lady, by her return of a gift of diamonds with the request for Ruskin's works instead. Such girls as that and such women as she, are indeed sadly rare. While teaching the starving Irish to dye and weave, and at the same time carrying on any amount of other work among the poor of London, this many-minded woman has also kept her place in the best society of London, has been an art-lover and worker and a student of the social life and handicrafts of nearly every country of the world. But our explanation of this allusion in a medical journal consists in the fact, known to but few, that Mrs. Hart before doing these things had passed with the highest honors the most rigorous examinations of the medical faculties of Paris, and by thorough hospital service had completed a perfect knowledge of medicine both theoretic and practical. Wherever she goes physicians should vie with others in hastening to do her will, and to do her honor!

When Rogues Fall Out, etc.—According to the *Summit County Beacon*, of Akron, Ohio, we learn that the Cuyahoga Falls (Ohio) Keeley Institute has sued the Marysville (Ohio) Keeley Institute for $100,000. The plaintiff states that he has paid to the defendant $30,000 in cash and $49,000 in stock, besides agreeing to pay a bonus of $20 for each patient under treatment, upon the representation that the defendant had paid the original Keeley Company $100,000 for the privilege of the exclusive use of the treatment in the State. It had further been claimed that with 600 patients a year a dividend of 34.16 per cent. could be declared, and with 1000 patients a dividend of 74.16 per cent., and also that the number of "lapses" would not exceed 5 per cent., whereas they exceeded 25 per cent., and among the first hundred 40 per cent. Finally, it had been claimed that the morphin-cure was absolute, whereas it proved entirely worthless. Surely the bottom of Keeleyism has fallen out. A deluded public will now be ready to turn to legitimate medicine until a new miracle-worker appears. As the mine had been pretty well worked out the suits for libel against the London *Lancet* and the London *Medical Press and Circular* were naturally withdrawn.

School Outhouses.—Although it has been enacted that boards of school-directors and controllers in the State of Pennsylvania shall provide suitable and convenient water-closets for each of the schools under their official jurisdiction, not less than two for each school or schoolbullding where both sexes are in attendance, in their respective school-districts, with separate means of access for each; and, unless placed at a remote distance one from the other, the approaches or walks thereto shall be separated by a substantial close fence not less than seven feet in height; and it shall be the duty of the directors or controllers to make provision for keeping the water-closets in a clean, comfortable, and healthful condition; there is reason to believe that this wise legislation is not everywhere throughout the State adequately administered. The merits of the law are so perfectly obvious that we should think the mere suggestion of delinquency should stimulate those in authority to its effective administration.

An Appeal to the People, through the advertising columns of daily (lay) newspapers, is being made to further the sale of the "Animal Extracts, prepared according to the process and under the supervision of Dr. Wm. A. Hammond." An extensive advertisement appeared in the advertising columns of the Chattanooga *Daily Times*, of January 19, 1894. Comment is unnecessary!

SELECTIONS.

TAXING PROPRIETARY MEDICINES.

The Ways and Means Committee of the House of Representatives has recommended the restoration of the tax on proprietary medicines. If to the tax the printing of the ingredients on the label would be required, much could be accomplished in the interest of the people and the profession. In this way this subject is regulated in European countries. Some of the preparations have value and can be used by the public with safety, while many of them are not alone dangerous, but worthless, and their sale is dependent entirely upon the fradulent claims to cure everything, in their advertisements. In fact, if this advertising was stopped, they would find no sale, and just in proportion as it is pushed, are they sold. They appeal to the hopes and fears of the sick and afflicted, and it is the obtaining of money under the worst kind of false pretences, and is really nothing more or less than robbery. While Congress is engaged in this business, would it not be well to tax the itinerant practitioner and vender of nostrums, with show-

accompaniments? They go from one State to the other, and the question naturally arises whether this is not one of inter-state commerce, that should be regulated by Congress. It is the policy of this class of frauds not to stay too long at one place, or to return at too short intervals to the same place, for the reason that it takes time to secure a fresh crop of dupes.—*Journal of the American Medical Association.*

ENGLISH AND AMERICAN JOURNALISM COMPARED.

From this condemnation I desire to exclude the literature of our American brethren. The country which has given to us the *Index Medicus* and the *Index-Catalogue* of its splendid library is not likely to fail in knowledge of the history of medicine. A knowledge of the work of others that is nearly always honest and thorough is as common in the best American medical literature as it is rare in our English journals. The man who writes on his own experience and knowledge writes on a poor and narrow and shifty foundation. In science he is to be found only in medicine; and in scientific medicine he bears the prefix—in all its significations—British.—*From Presidential Address of* J. Greig Smith, *on Modern Medical Journalism; Bristol Medico-Chirurgical Journal.*

REVIEWS.

Chemistry and Physics: A Manual for Students and Practitioners. By Joseph Struthers, Ph.B., D. W. Ward, Ph.B., and Charles S. Willmarth, M.S. (The Students' Quiz Series, edited by B. B. Gallaudet, M.D.) Philadelphia: Lea Brothers & Co., 1893.

This is a neatly printed, small octavo of two hundred and seventy-nine pages, with an index and numerous good illustrations. It is arranged in questions and answers, a method that has been often adopted in works of this class, but concerning the advantage of which there is room for argument. The work, of course, is primarily intended to meet the wants of students taking chemistry as part of a general collegiate, medical, or dental course. It is a compilation from standard text-books, and the merit of such a work lies essentially in the judgment and accuracy with which the selections are made. The combination of physics with chemistry renders the volume rather more widely useful than a compend of chemistry alone, and as many medical schools are now requiring an entrance examination in physics, the medical student will find the book useful in the pre-college year. The text is generally correct. We note with regret the use of the old spelling, and the occasional occurrence of such objectionable names as "bisulphate of potash," "bicarbonate of sodium."

The organic chemistry occupies sixty-seven pages, presenting a good summary of this extended field. The recent investigations on the structural formulæ of the sugars might have been presented more clearly, and the necessity of great condensation has rendered the text in rare instances rather vague. There is no section on clinical chemistry.

Treatment of Sterility in the Woman. By Dr. de Sinéty. Translated by E. P. Hurd, M.D. (The Physicians' Leisure Library.) Pp. 130. Detroit, Mich.: George S. Davis.

The cure of sterility in the female is one of the most vexing and perplexing problems with which the physician is called upon to deal, and its causes are of such a varied nature that unless one's mind is refreshed by some such summary as is presented in this brochure, the true etiology of any one case may readily be overlooked. It should always be borne in mind—and the author fails to mention this—that the sterility is very frequently the result of a lacerated perineum with an associated lack of retentive power of the vagina, so that there is an almost immediate escape of the semen. In such cases perineorrhaphy is very likely to be followed by most happy results. Dr. de Sinéty has given us a systematic and interesting symposium on an important gynecologic condition, and his book has not suffered deterioration at the hands of his translator.

International Clinics: A Quarterly of Clinical Lectures on Medicine, Neurology, Pediatrics, Surgery, Genito-urinary Surgery, Gynecology, Ophthalmology, Laryngology, Otology, Dermatology, etc. Edited by John M. Keating, M.D., LL.D.; Judson Daland, M.D.; J. Mitchell Bruce, M.D., F.R.C.P.; David W. Finlay, M.D., F.R.C.P. Vol. III, Third Series, 1893.

This volume of *International Clinics* fully sustains the enviable reputation made by preceding volumes. The high standard originally set is faithfully adhered to, and the result is the presentation of an interesting panorama of practical medicine of the hour. The contributions come from many parts of the scientific world though, naturally, the larger number are by American teachers. This latter fact, however, cannot be understood to imply any detraction from the merits of the work, for it will be conceded by impartial minds that there is no people that excels the American in practical matters.

Lack of space prevents even the mere mention of the titles or of the names of the authors of the forty-eight papers contained within this volume, and a sense of delicacy forbids the selection of any number for comment. We can, however, truthfully say that the collection of papers is, as a whole, an interesting and instructive one, and reflects great credit upon contributors, editors, and publishers. Twelve plates and twenty figures illustrate the text.

Manual of Physical Diagnosis. For the Use of Students and Physicians. By James Tyson, M.D., Professor of Clinical Medicine in the University of Pennsylvania, etc. Second edition, revised and enlarged. 8vo, pp. 241. Philadelphia: P. Blakiston, Son & Co., 1893.

The deserved approval that has been accorded Dr. Tyson's little manual is indicated by the appearance of a second edition two years after the first. We need not here repeat our previous favorable criticism. We are glad to note that the number of pages has increased from 136 to 241, and the number of illustrations from seven-

teen to thirty-three; that sections have been added on the use of sphygmograph and cardiograph in diagnosis, as well as a chapter on physical examination of the abdomen; besides an appendix detailing methods of making examinations of blood and sputum, of the gastric contents, and of making post-mortem examinations. The popularity of Tyson's *Physical Diagnosis* will be enhanced by this revision.

Hysterical Women: Trials, Tricks, Tears and Tantrums. By A. W. Thornton, M.D. Chicago: Donohue & Henneberry, 1893.

A book with a sensational title, with a most sensational frontispiece representing a physician dashing cold water on a patient in hysterical convulsions, surrounded by excited friends, this work has little to commend it, and much that should be severely criticised. It may be imagined that "remarkable cases" and "remarkable cures" are selected and detailed. The author has, he states, written mainly for "the million," and he has certainly selected his material with an eye single to this purpose. There is no attempt to define or to make clear the nature of hysteria; and the oft-repeated methods of cure by cold water, sternness, and the like, evidence the lack of appreciation of hysteria as an actual disease.

An Outline of the Embryology of the Eye, with Illustrations from Original Pen-Drawings by the Author. By Ward A. Holden, A.M., M.D., Assistant-Surgeon, New York Ophthalmic and Aural Institute, etc. The Cartwright Prize Essay for 1893. New York: G. P. Putnam's Sons, 1893.

Notable among the many bright and rising students of ophthalmic science is Dr. Holden, who is to be congratulated upon the preparation of this most excellent monograph on the subject expressed in the foregoing title. The beautiful little volume is illustrated with engravings that are a credit to both author and publisher.

Differential Diagnosis of Common Diseases of the Eye: Designed for the Use of General Physicians. By W. F. Conners, Oil City, Pa., 1893.

This is a chart about 12 x 15 inches, designed to be hung on the wall, and to aid physicians without instruments and the specialist's knowledge, to make a diagnosis of common eye-diseases. We commend it.

CORRESPONDENCE.

THE MEDICAL EXAMINERS.

To the Editor of The Medical News,

Sir: The Medical News of January 27th, in an editorial comment upon the State Board of Medical Examiners law, says: "Pitiful as must be the tacit admission by those who may not have thought seriously upon the subject, that there can be more than one kind of medicine and one kind of physician, it is still a source of congratulation that at least the worst forms of incompetence and downright quackery will no longer find the soil of Pennsylvania adapted for their propagation."

If the medical press in general had been as loyal to the cause of true medicine and had shown the earnestness of spirit in its defence that has been shown by The Medical News the profession could have escaped this "tacit admission" that there can be more than one kind of medicine.

Instead of congratulation, however, Mr. Editor, that at least the worst forms of quackery will no longer find the soil of Pennsylvania adapted for their propagation, we recognize with regret and chagrin that the Examiners law is formulated to aid in propagating the worst forms of quackery, namely, those forms which claim incorporation, vested rights, etc., and the technical resources that follow in defence of such claims. There is but one kind of medicine and but one kind of physician so long as we have an educational requirement for the physician, provided the physician determines to assert his rights. If the educational qualification has meaning, the educated medical profession is the medical authority as well in therapeutics as in all other medical questions.

The medical profession, not the State or the people, is the authority which must and does decide that we have but one kind of medicine, one kind of physician, and one kind of therapeutics. Therapeutics belongs to the department of medicine, and questions in relation thereto are to be decided by the medical profession, not by the General Assembly, nor by any other than medical authority. But this Examiners law authorizes the Governor to appoint a board of examiners to be composed of homeopaths because the homeopath declares he has a therapeutics upon the basis of the theories of Hahnemann, and that he has a college chartered by the State with power to confer degrees upon the basis of these theories. If the State grants a charter for a medical college, however, with power to confer degrees upon the basis of theories which, by the medical world, have been declared of no value as a therapeutic basis, such a college is incorporated by the State either in ignorance or in disregard of the decision of the medical profession, which, by right of education, is the medical authority of the State.

The medical profession is as undeniably the highest medical authority as is the Supreme Court the highest legal authority, and a judicial decision should here be obtained as to the prerogative of the medical profession, whether or not by right of education its decisions should be respected as the medical authority of the State, and whether or not a medical college can be declared to be legally incorporated which adopts as an educational basis, and by its charter is authorized to confer degrees upon the basis of theories that have been rejected by the medical profession of the world.

A half-century has elapsed since a charter, the first in the world, was granted in Pennsylvania at the request of those claiming to be homeopaths, under which they claim the right to confer degrees upon the basis of the theories of Hahnemann, and during all this time no move has been made by the profession to assert its prerogative in a test of the legality of the incorporation of such a college. Even when a law is passed authorizing the homeopath to receive a license as a competent physician after being examined by a board of homeopaths, the Governor can find members of the medical profession of high intelligence and good professional standing who

yet seem to be willing to still continue this pusillanimity or imbecility as the policy of the profession, and who as members of a board of examiners are willing to coöperate with representatives of incorporated quackery in enforcing this abortion of medical legislation called a Medical Examiners law.

Duty to the public requires the profession to assert its prerogative and secure a legal decision as to the right of a college to employ as an educational basis the rejected theories of Hahnemann, as well as the right of the State to accept the degree of such a college as an evidence of educational qualification for a competent physician.

We may say of the gentlemen named by the Governor as examiners, if they do not know that the man who adopts the theories of Hahnemann as the basis of his therapeutic methods is not a competent physician, that they are themselves not competent to act as examiners, and if they possess that knowledge they should assuredly not coöperate in executing a law which authorizes such men to receive a license as competent physicians.

We have here, Sir, a condition, not a theory. If amiability supplants sagacity, and the gentlemen consent to serve as a board of examiners, the graduates of our colleges by contributing one dollar each instead of paying twenty-five dollars for an examination can have the law set aside by any court in the Commonwealth, not even excepting our Orphans' Court with the President Judge on the bench.

As our medical colleges cannot be said to be in affiliation with the profession and with the colleges of other States, while the faculties are committed to the support and are willing to aid in enforcing a law which authorizes homeopaths to receive a license as competent physicians, we hope the members of these faculties will lose no time in placing themselves on record as opposing this law, the execution of which is in conflict with the medical authority which colleges in good standing are required to support.

S. UPDEGROVE.

PHILADELPHIA, January 29, 1894.

THE ADMINISTRATION OF HEALTH-ORDINANCES.

To the Editor of THE MEDICAL NEWS,

SIR: Desiring to learn something concerning the health-ordinances in force in the city of Philadelphia, I recently applied to the Health-Officer for a circular or pamphlet containing such, and was surprised to learn from him that no such collective pamphlet exists, that only by searching through the several annuals, dating back, I suppose, to the earliest times, and by wading through a mass of digests and commentaries, could I obtain a knowledge of the laws I am supposed to obey. Possibly there has never been a demand such as I have made. As is usual with all ordinances, no one seems to care for them after they have once been brought into existence; but health-laws must and should be common knowledge. A tenant, for instance, ought to know what authority the Board of Health possesses over his landlord.

A citizen ought to be aware of the laws respecting various nuisances. Physicians especially ought to know what rights they have or can use in correcting unsanitary conditions. I have reason to believe that were the present statutes enforced many of the evils of the "slums" would be done away with, many hovels, breeding-places of disease, would be torn down, and the filthy condition of some of the courts and streets an impossibility; but no one seems to know—I mean, among the citizens—what the laws on the subject really are, and, therefore, they do not insist on their enforcement or aid in calling the attention of the proper officials to possible neglect of duty. It seems to me that here would be a good beginning for active propaganda in the education of citizens in public hygiene. Let such an organized body as the County Medical Society, or the College of Physicians, or the journal you, Sir Editor, have the honor to direct, prepare for public distribution copies of the more general health-ordinances now in force; let them be printed in various languages, and plainly worded, and let them be given a wide distribution and circulation.

From time to time, as new laws are made or old ones repealed, a revision of such a circular would have to be made. How foolish to expect a community so composite as this one to be sanitary, when the first principles of sanitation are unknown to the majority of its members.

What society or corporation could exist without making known to its members its vital and governing laws? Every one of us must have violated these health-ordinances time and again, yet had we been apprehended for such violation ignorance would not have been a valid excuse. Medical societies and medical journals can do very much to inaugurate a practical system of hygienic education of the public, and to aid and maintain it. It is as necessary during ordinary times as in epidemics of smallpox and cholera. Respectfully,

M. V. BALL, M.D.
RESIDENT PHYSICIAN, EASTERN STATE PENITENTIARY, PHILADELPHIA.

[Certainly the Board of Health should have at hand, together, all of the ordinances that appertain to its functions as an administrative body, and it should further see that the community is made to know of the existence of these ordinances and of their requirements in order that they may be enforced, either voluntarily or upon the authority of the Board.—ED. NEWS.]

NEWS ITEMS.

The Medical Society of the District of Columbia will celebrate the seventy-fifth anniversary of its organization in Washington, on Friday evening, February 10, 1894. The following program has been arranged:

"Invocation," by Rev. Wm. A. Bartlett, D.D.

"Address by the President," Samuel C. Busey, M.D., LL.D.

"Address of Congratulation," by Theophilus Parvin, M.D., LL.D. (Representative of the College of Physicians of Philadelphia).

"Address—History of the Medical Society of the District of Columbia," by Wm. W. Johnston, A.M., M.D.

"Address—History of the Hospitals of the District of Columbia," by J. Ford Thompson, M.D.

"Address—History of the Medical Colleges of the District of Columbia," by Thompson C. Smith, M.D.

Mathews' Medical Quarterly, a journal devoted to diseases of the rectum, gastro-intestinal disease, and rectal and gastro-intestinal surgery, has made its first appearance. It is published at Louisville, Ky., and is owned and edited by Dr. Joseph M. Mathews, with Dr. Henry E. Tuley as Associate Editor and Manager. The first number contains 186 pages, and includes sixteen original articles by well-known writers, together with reports of society meetings, editorial articles, and abstracts from current medical literature. The editors request the names of all reputable surgeons in the United States that limit their practice to the treatment of diseases of the rectum. The new venture deserves to succeed.

The Effects of Medical Legislation.—At the last meeting of the State Board of Medical Examiners of the State of Washington, held in Seattle, there were twenty-two applicants for a license to practise, of whom twelve failed to pass the required examination and were rejected. The Board now requires a general average of 75 per cent. on all branches, a rise from its former standard, and soon the standard will be raised to 80 per cent.

Dr. Ch. E. Quinquaud, member of the French Academy of Medicine, Professor Agregé of the Paris Faculty, Physician to the Hôpital Saint-Louis, Chevalier of the Legion of Honor, died on January 9th, at the age of fifty-two years.

Adolf Heider, Assistant in Hygiene in the University of Vienna, died recently of meningitis in the sequence of an attack of influenza complicated by pneumonia.

Dr. Frank D. Beane, of New York City, died at Lake North, Fla., in his forty-third year, on January 6, 1894, of remittent fever.

Dr. Murdoch Cameron has been appointed to the vacant chair of Midwifery in the University of Glasgow.

Heubner, of Leipzig, has been elected the successor of Henoch in the chair of Pediatry at Berlin.

Dr. Paul Diday, the distinguished French surgeon, died on January 9th, at the age of eighty-three years.

Van Beneden, the celebrated Belgian naturalist, died recently at the age of eighty-five years.

OPERATIONS FOR THE CORRECTION OF INVETERATE PES VARUS.[1]

BY G. G. DAVIS, M.D., M.R.C.S.,
OF PHILADELPHIA;
SURGEON TO THE GERMAN AND ST. JOSEPH'S HOSPITALS; ASSISTANT SURGEON, ORTHOPEDIC HOSPITAL.

IN the treatment of the most severe cases of varus, the profession, as a rule, admits that operations on the bones themselves are necessary, and that these operations are to be either excision of the astragalus alone, or of a wedge-shaped piece of bone sufficient in size to allow straightening of the foot. The choice of procedures having been narrowed down to these two, I believe the wedge-shaped resection offers so many advantages as to command the preference. Excision of the astragalus alone I believe to be an unnecessary procedure when it proves effectual in removing the deformity; and when operation on the bones is required, the removal of this bone alone will not prove an efficient and satisfactory mode of treatment. I recently had a most satisfactory case illustrating the two operations.

The patient is a boy, twelve years of age, with marked varus of both feet. He had been unsuccessfully treated in infancy by division of the tendons. His right foot was turned inward until parallel to a line drawn through the two malleoli, and the sole was vertical (see Fig. 1). He walked on the outer border. The left foot was similar to the right, but the deformity was less marked in degree. On account of the right foot showing the more marked deformity, I operated on it by wedge-shaped resection, while for the purpose of making a comparison of the two operations, Dr. Goodman performed an excision of the astragalus on the left.

The plantar fascia of the right foot having been divided subcutaneously, the sole was thoroughly stretched and the incision for the wedge-shaped resection made from just anterior to the external malleolus to the tuberosity of the fifth metatarsal bone. The peroneus longus and brevis were pushed backward and the peroneus tertius forward. With a chisel and elevator a wedge of bone was then removed through the entire thickness of the tarsus. The anterior line of section passed through the cuboid bone and the posterior portion of the cuneiform bones. The posterior section traversed the anterior portion of the calcaneum and the neck of the astragalus. This enabled the foot to be brought perfectly straight, with the sole resting flat on the ground (Fig. 2). The foot healed nicely in this position, and never afterward troubled him.

FIG. 1

Right foot previous to operation.

FIG. 2.

Same foot after correction by wedge-shaped resection.

In the other foot the astragalus was removed by a long dorsal incision, and healing also occurred promptly. In this foot, notwithstanding the division of the plantar fascia and the anterior and posterior tibial tendons while the sole was brought into a horizontal position, the incurvation and hollowing-out persisted, so that when the operation was finished a considerable amount of deformity still remained (Fig 3).

FIG. 3.

Left foot after excision of the astragalus.

The results which I have seen in these as well as in many other cases, have so firmly convinced me of the superiority of the wedge-shaped resection, when judiciously and skilfully performed, that I think resection of the astragalus alone, as a means of treatment of these most obstinate cases of varus, should be absolutely abandoned. I see no field for it which is not better filled by other measures. Almost

[1] Read before the College of Physicians, Philadelphia, December, 1893.

all surgeons agree in admitting that the removal of some bony tissue is necessary to correct the malpositions that are sometimes found in cases between the ages of, say, twelve and fifteen or more years. The

operations both of removal of the astragalus and of wedge-shaped resection have been largely abused, and the former more than the latter. Removal of the astragalus has obtained its greatest reputation in cases in which no operation on the bones themselves has been required. Even children a year and a half old, and under, have been subjected to that unnecessary mutilation. Those cases in which it has been successful in removing the deformity, I am disposed to regard as being curable by tenotomy, with forcible straightening under anesthesia, and the immediate application of a plaster bandage; this procedure being repeated if necessary.

As an evidence of what can be accomplished by conservative treatment, I show this boy of six years. On admission his feet were as illustrated in Figs. 6 and 7. They were directed inward toward each other, on a line passing through the malleoli; the soles were vertical, and he walked on the outer edge of his feet, with his fourth and fifth toes completely doubled under. By means of tenotomy and forcible straightening with the hands, under anesthesia, three times, and then applying plaster bandages, his feet, in the course of three months, were brought perfectly straight, braces being used to prevent relapse. This was a case in which many surgeons would have removed the astragalus, but events proved that a cure could be effected without such removal.

I also show you an astragalus removed by another surgeon from a child six years of age. The abnormal bending inward of the neck is well shown. When we examine the bone we find it so soft that I am able to thrust this pin through it in various directions with my fingers. What justification there can be for the excision of the astragalus in such cases I cannot see. The removal of this bone for the correction of pes varus seems to me to be a very illogical procedure. In a foot already shortened on its inner side, the main bone on that side is removed, while the outer side is allowed to remain intact. The deformity is not confined to the astragalus, but the condition and position of the calcaneum and cuboid are likewise altered. The main arch of the foot is composed of two subsidiary arches, an outer and an inner, which are united behind in the calcaneum. The inner arch comprises the calcaneum, astragalus, scaphoid, and cuneiform bones, with the inner three metatarsals. The outer is composed of the calcaneum, cuboid, and outer two metatarsal bones. The outer arch participates in the deformity to as great an extent as does the inner, if not to a greater extent, and when the astragalus bone of the inner arch is removed the outer arch is still left intact, and in these obstinate cases it is of sufficient strength to still retain the foot in its distorted position of inversion.

When one attempts, by removal of the astragalus alone, to correct a case that is suitable for operation, he at once finds that it is impossible to remove the deformity without proceeding farther; and, first, the external malleolus is chiselled off, then an osteotomy of the calcaneum or cuboid is per-

Feet of a boy, aged six years, cured without operation on the bones.

formed, or, finally, a piece of bone is removed, the operation thus practically becoming a wedge-shaped resection. I asked a surgeon once if he could always bring the foot straight by removal of the astragalus, and he said "No." "Then what do you do?" said I, and he answered: "Go on removing bone until I can bring it straight"—and if the proper cases present themselves to the surgeon that is just what he must do. The greatest objection to the removal of the astragalus alone is that it is unnecessary in the less severe cases, and in the bad

ones it fails to remove the deformity. The foot is likely to remain inverted and to retain the projection of the dorsum and the exaggerated hollow of the sole which it possessed before the operation, and which is shown in Figs. 3 and 5. As time passes, the condition at the ankle will probably be satisfactory, but the inversion of the foot, if not carefully guarded against, may become worse, or at least fail to improve, and the patient still be badly crippled. I also believe that after excision of the astragalus at times—particularly if any marked motion remains at the ankle—control over the foot is more likely to be partially lost, causing the toes to drop and the foot to invert in the same manner as is seen in cases of paralysis of the extensors in anterior polio-myelitis. It is objected that wedge-shaped resection mutilates the foot too much, but this is not so, because it is only performed in the already extremely deformed cases. In this boy, the foot on which the operation of wedge-shaped resection was performed, although originally worse than the other, is not only a nice, straight, flat foot, but it is absolutely greater in length than the one in which the astragalus only was excised. The difference in length in favor of the wedge-shaped excision is fully three-quarters of an inch. In fact, the deformity remaining in the foot in which the astragalus has been removed is so marked even now, two years after the operation, that it is necessary for the boy to wear a brace to keep the foot from again becoming worse, as without it the foot turns in and the boy walks on its edge, and, if he persisted, would soon have it completely turned over so as to walk on its dorsum. The condition is so dubious that if not carefully watched it may even yet require an osteotomy or resection of bone to such an extent as may be sufficient to make it a respectable and reliable organ of locomotion.

The tendency among orthopedic surgeons in the treatment of marked cases of club-foot is toward conservatism and the avoidance of operative procedures on the bones; but the plaster cast that I now show you (Fig. 8) of my first case of wedge-shaped resection, from a man aged twenty-one years, will, I am sure, convince you that such enormous and inveterate distortions and deformities cannot be satisfactorily treated by mild measures alone.

Mr. Brodhurst, in his recent brochure on the treatment of club-foot, strongly condemns tarsotomies and tarsectomies. The utmost limit to which he is willing to go is shown by the following quotation: "There are, however, certain cases, and among thousands perhaps as many as could be counted on the fingers of one hand, where it would be permissible to remove the astragalus." He therefore admits that operations on the bones are sometimes justifiable, but I cannot agree with him, for the reasons given, in thinking that the operation chosen should be the removal of the astragalus alone. He quotes Mr. Walsham, as follows: "I have always taught that, though I firmly believe these intractable grades of the deformity can only be cured by tarsectomy, at the best it is but a bad

Fig. 8.

Club-foot in a man aged twenty-one years.

Fig. 9.

Same after wedge-shaped resection.

job." From this I must dissent, and I do not believe that any fair minded surgeon would characterize the results in the cases which I have shown as being, to use Mr. Walsham's expression, "a bad job." (Fig. 9.)

Dr. Ogston is also quoted to the effect that "Tarsotomy by subcutaneous puncture and chain-saw was performed five times, but is now given up. Excision of a wedge of the tarsus was performed three times, and, though it looked pretty, was not useful." If reducing very greatly the amount of deformity and enabling the patient to conceal the remainder, and giving him a painless and satisfactory foot on which he can walk without the aid of braces, is not a "useful" procedure, then I would like to know what constitutes usefulness. If the operations cited were all performed on a single case it would be a hopeful man indeed who would expect a "useful" foot to result, and if Mr. Brodhurst forms his opinions of the value of the operation in properly selected cases on such procedures as the foregoing, and the method as witnessed by Senn, and described by him in his *Four Months Among the Surgeons of Europe*, then we can readily account for his bad opinion of it. As for myself, I respectfully decline to accept such chain-saw surgery as being the criterion by which to judge of the value of this operation.

255 South Sixteenth Street.

The Medical Society of the District of Columbia will celebrate the seventy-fifth anniversary of its organization in Washington, on Friday evening, February 16, 1894 (not February 10, as inadvertently stated in The News of February 3).

IS OPERATION DEMANDED IN ALL CASES OF APPENDICITIS?—THE BEST TIME TO OPERATE.[1]

By A. MORGAN CARTLEDGE, M.D.,
of Louisville, Ky.

Disease of the vermiform appendix is probably attracting more attention at the present time than any pathologic condition within the abdomen. So-called typhlitis and perityphlitis have ever been considered common maladies, but the revelations of the appendix as a disease-producing factor in these troubles are of very recent years. If the number of the human family that have been quietly borne to mother earth with the physician's verdict of death from peritonitis, inflammation of the bowels, etc., could be traced, the aggregate would be appalling, and yet modern operative surgery and modern post-mortem investigation demonstrate beyond doubt that 95 per cent. of males, and not a few females in this list, perished of conditions having their origin in the vermiform appendix. The idea that the cecum and its supporting serous and connective tissue are the most frequent seat of trouble had become so fixed in the mind of the profession that every advance from this foggy pathology met with strong resistance. When Sands, Treves, and others called attention to the frequency of the appendix as a starting-point in these inflammations, their statements attracted little attention and in many instances were denied. Again, when surgery demonstrated that disease of this structure was essentially intra-peritoneal, hence the organ in most cases was an intra-peritoneal one, we were charged with stretching the normal human anatomy in order to bring within the abdomen a structure that did not belong there.

Most modern surgeons have an abiding faith in the surgical maxim that whenever pus is believed to be present in the tissues or organs of the body an effort to remove it should be made. Hence the new pathology of a very old and frequently fatal malady inspired surgeons to attempt some radical means of relief. In the enthusiasm that followed, probably some lives were sacrificed that would otherwise have been prolonged, yet this feature is one that has occurred in the evolution of every great life-saving operation in surgery.

Perfection in technique can only come from individual experience and a knowledge of the work of others. The same principle applies to numerous other requisites of success, such as diagnosis, advisability of operation, and time of operation.

The diagnosis of appendicitis has been about as nearly perfected as that of most other surgical lesions; the question to be settled at the present time is as to the prognosis and treatment. If appendicitis had a more uniform clinical course, discussions would be less heard of, and yet most surgical conditions have just as many clinical and pathologic variations as this disease. It matters little to the surgeon whether a tuberculous osteitis in the head of the tibia is going to remain localized for some time, or whether it has perforated the periosteum, medullary canal, or the joint; all he recognizes is his diagnosis; his treatment is based upon such plain surgical principles as not to permit of discussion. Yet, fifteen years ago such cases were treated by various expectant methods until operations were demanded, often too late to be of use. Why did surgeons and physicians formerly apply iodin-blisters and liniments to inflammatory foci in bone? Simply because the necessary rest of such treatment often caused an abatement of symptoms and gave a false impression of cure. The patient walked again without pain, but if he lived long enough inevitably had an aggravated recurrence of his trouble.

At the present time we are repeatedly told that appendicitis rarely kills, and that nearly all cases spontaneously recover. The pathology of a disease is the only true keynote to its rational treatment. Probably the best classification of appendicitis is:

Catarrhal	(simple).
Ulcerative	(from tuberculosis). (from foreign bodies).
Perforating	(from ulceration). (from strangulation, the result of volvulus of the appendix).

The classification deals strictly with the changes occurring in the appendix, and should be considered separately from the peritoneal and other conditions that may ensue, and that may cause well-marked variations in the clinical course of the disease. From a low-grade ulceration, say the result of the presence of an enterolith, the irritation, long-continued, will probably lead to extensive circumscribed peritonitis with a firm tumor composed exclusively of recent fibrous tissue. If imbedded in such a mass, the walls of the appendix give way, the pus that forms is rather securely encapsulated, and may be days, weeks, even years, finding an outlet. In fact, as is often the case, if the bacillus coli communis predominates in the pus, it may remain so encapsulated until it receives a new impetus of irritation. Case VIII of my operated cases illustrates this:

W. D., a boy, eleven years old, was seized with pain in the appendicular region at 6 P M. On being questioned by his parents he admitted that another boy had struck him there with a ball made of partly melted snow during the afternoon. This was on Wednesday; the family physician was summoned

[1] Read before the Southern Surgical and Gynecological Association, 1893.

Thursday morning and found the patient with flexed legs; the abdomen swollen and very tender, especilly in the right side rather high up; there was great pain, a rapid pulse, and a temperature of 103°. Hot fomentations were applied and opium was given. On the evening of the same day the boy was no better and a cathartic was given. On Friday morning the pulse was 130, temperature 103°, abdominal swelling increased and general, and no movement of the bowels; salines were given, followed by both low and high enemas, but there was no response. I saw the patient in consultation Friday evening at six o'clock, and found him with a pinched expression, almost moribund, the pulse from 140 to 150, enormous general abdominal distention, jerking respiration, and frequent projectile vomiting of green serum. Diagnosis: probable intestinal obstruction from intussusception or volvulus.

I never refuse (as my statistics of death show) to operate provided there is any pulse, if I believe intestinal obstruction exists; hence, with an explanation of the situation I did so in this case. On opening the tense belly, by a median incision, there was a gush of fetid pus and distended coils of intestine. A few gallons of hot water were used for irrigation and an attempt made to locate the trouble. Dense adhesions were encountered on the right side, extending from the iliac fossa behind and beside the ascending colon, as high as the liver. These adhesions were clearly old. Breaking through with my finger, fetid pus in increased volume came from that side. I had only been at work some five minutes when the condition of the patient warned me that I must quit or have a death upon the table. I hastily flushed the cavity, made additional drainage-points in which gauze was inserted, surrounded the tube with gauze from the median cut, and closed the abdomen. The little patient died at four o'clock the following morning from a continuation of the sepsis and intestinal paresis. The autopsy revealed numerous old adhesions and an abscess-cavity around the appendix, which had nearly sloughed away. The mesenteric glands were enlarged, and the evidences were clear of a general suppurative and adhesive peritonitis. After the operation, and before the autopsy, I suspected the trouble, for I felt the enlarged glands and noted the ancient character of the adhesions. The family was questioned as to the boy's history. He never was sick but once before, and that was eight months previously, when he had what the attending physician (not his present one) called typhoid fever. During this sickness, which lasted two weeks and came on suddenly, he complained of great pain in the right side. How many cases of this disease have been treated for typhoid fever cannot be told.

Explanations to the family were very much in order in this case, as they naturally believed the boy was killed by the ice-ball thrown by his companion. This boy died of peritonitis, the result of a ruptured abscess around an old perforative appendicitis. The rupture was no doubt precipitated by the blow of the ice-ball. Change the age and principle of crime involved, and we would have an interesting legal point to decide.

Two other cases under my observation, developed within a few hours after an injury, and gave the history of being below the health-standard prior to the accident, and left little doubt in my mind as to the true part that injury plays as an exciting cause in this affection.

To return to our classification. We know more about the pathology of ulcerative or suppurative appendicitis than we do of the catarrhal variety. Why? Because the cases not operated upon and that recover are mostly called catarrhal. These are the cases that progress with little pain, very little fever, 101° F. as a maximum temperature, and a tumor that subsides. These cases are the pride of the poultice-and-opium doctor. I do not believe that it is possible for a catarrhal inflammation, which must of necessity be confined to the mucous coat of the appendix, to produce such peritoneal proliferations. If there is anything in reason, anything in the similarity of action of like tissues under the same conditions, then this is impossible; for nowhere in the body will a catarrhal inflammation of mucous membrane cause dense deposits in the adjacent peritoneum. By catarrhal appendicitis is meant that possible variety found at autopsies after death from other causes, and also found by some surgeons after operating upon individuals with pain in the right iliac fossa.

Our knowledge of catarrhal inflammation of the appendix is, then, derived from two sources: *First*, the cases not operated upon and called so, though never seen; *second*, from cases operated upon by surgeons who find the appendix not diseased, or who, finding it tense and distended without peritoneal adhesions, call the condition catarrhal appendicitis. If many of the latter cases were examined, ulcerative changes would be found taking place, with, probably, stenosis at some part of the lumen, the distal part rapidly filling with the unemptied secretion of the appendix. Such an appendix, if there was great pain, would probably have ruptured before adhesions formed. The result of the rupture is one of two things, depending upon the composition of the effused liquid: If free from pus-forming organisms, circumscribed peritonitis, and later, abscess. If containing pus-organisms from intra-appendicular suppuration, a diffuse fatal peritonitis would follow.

Ulcerative appendicitis must be either tuberculous or traumatic, the trauma resulting from the presence of foreign bodies and enteroliths, usually the latter. The tuberculous variety (probably more common than formerly supposed) would give rise only to acute symptoms as the result of cicatrization and stenosis with distal distention, or as a result of secondary infection with pus-organisms, either of these results favoring perforation. This is essentially the

chronic variety, but it will eventually lead to peroration in the ways indicated.

Volvulus, or rotation, furnishes most of the *furor* cases of appendicitis, those that come without premonition. This condition properly should not be classed as appendicitis, the appendix giving way as a result of rapid necrosis from arrested blood-supply, and the general peritonitis that ensues being almost the first symptom observed. I have seen one such case saved by timely operation. There was so little time between the rupture and the operation (four hours) that an absence of peritoneal inflammation permitted a perfect examination as to the true nature of the trouble. One such case throws more light upon the pathology of the disease than many hundreds operated upon at the usual time when the origin of the appendicular lesion is much obscured by peritoneal changes.

As to the prognosis, while we accept as true all the favorable statistics offered for appendicitis, they are favorable from one point of observation only; that is as to the first attack, and then favorable only so far as the individual's life is concerned. When physicians come to view inflammation of the vermiform appendix in the proper light, the prognosis assumes a very different shade. We are accustomed to think of the appendix becoming diseased in the ways mentioned, then a perfect resolution taking place, and except for a slight predisposition, the individual being as healthy as before. This is certainly far from the truth. We should consider any appendix once so affected as to deserve the name of appendicitis, whether from tubercle or trauma, a permanently diseased structure; and fancied cures are but quiescent states, the result of very easily recognized conditions. Nature does wonders to bar the progress of this common affection, to render its results bearable by adjacent structures, and at last to get rid of its evil consequences; yet the plain fact remains that if there is no excuse for allowing removable tuberculous foci to remain elsewhere in the body; if it is considered good surgery to remove pus and pus-forming structures elsewhere, why is it good surgery to treat this disease by expectant methods?

If we could trace our so-called first-attack cases of appendicitis through subsequent ones, we would say the prognosis not only as to health and comfort, but also as to life, is bad, and very bad. A man has the trouble three, four, or five times, apparently recovers, and all are counted as cures, probably by different physicians. Finally he dies in an attack; the death is counted but once, and sometimes not then, for, as is often the case, if death results from the rupture of an unrecognized appendicular abscess, or from diffuse peritonitis after perforation, the chances are that the cause is never suspected and death is recorded as occurring from peritonitis.

There are thousands of physicians who know how many patients they have had recover from appendicitis without operation, but of this number few know the cause of the peritonitis that has carried away thousands of other patients.

Every man's experience, whether his best guide or not, will remain his most impressive one. If I should review condensedly the evolution of my views as to operative interference in appendicitis, it would be about as follows:

First. I thought operation rarely indicated.

Second. It would be well to distinguish between suppurative and catarrhal cases, operating on the former and not in the latter.

Third, and last. My present belief is that every case not barred by surgical limitations should be operated upon.

As to the *time for operation*, my experience again has no doubt been that of many others, namely, one of changing ideas. Less than a year ago I would have replied to this question by saying, In so-called recurring appendicitis, operate between the attacks. When perforation occurs with abundant adhesions, wait until anterior peritoneal adhesions form in order to be sure of working in a cut-off space. The time is generally in this type of the disease from the third to the tenth day, depending upon the intensity of the inflammation. This last rule was a pet one of mine. In the rapidly-perforating case or when a peritoneal abscess ruptures in the free cavity, operate at once.

My present rule is, provided the symptoms are not too urgent, to operate as soon as the bowels can be thoroughly moved. This opinion is based upon the accidents observed while waiting, and the knowledge that our technique is now competent to deal successfully with all clinical types of the disease, except the majority of those complicated by diffuse septic peritonitis, and these are they that most often ensue from delay.

CLINICAL MEMORANDA.

VAGINAL HYSTERECTOMY FOR CARCINOMA OF THE UTERUS PERFORMED BY ENUCLEATION WITHOUT HEMORRHAGE.

BY ROBERT REYBURN, A.M., M.D.,
PROFESSOR OF PHYSIOLOGY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF HOWARD UNIVERSITY, WASHINGTON, D. C.

ON November 16, 1893, I was invited, in consultation with Dr. J. F. Francis, to see Mrs. S., a widow, colored, aged seventy-two years. The diagnosis of uterine carcinoma had been made by the attending physician, and the object of the consultation was to devise some means by which the hemorrhage from the uterus (which had been very profuse) could be checked. The patient had had a number of attacks of hemorrhage from the uterus

prior to my being called in, and had one on November 15, 1893, which nearly proved fatal.

On making an examination the characteristic odor, the indurated cervix, and irregular ulcerated margins, left no doubt of the correctness of the diagnosis. The woman was removed to the Freedman's Hospital on November 18th, and on November 22d the operation for her relief was performed. It had been my intention to perform the usual operation of vaginal hysterectomy, well described by Dr. A. J. McCosh, in THE MEDICAL NEWS of November 4, 1893; and by Dr. E. E. Montgomery, in THE MEDICAL NEWS of November 18, 1893.

Twenty-four hours previous to the operation, I was placed in possession of a paper written by Dr. E. H. Pratt, of Chicago (a homeopathic physician, I believe), giving the histories of eight cases operated upon by him in which he had made a transverse incision just above the os uteri, into the layer of areolar or loose layer of cellular tissue that lies between the uterus and the vaginal mucous membrane covering the cervix, and by careful dissection had enucleated the uterus. The idea seemed to me to be admirable and I determined to forthwith put it into execution.

On November 23, 1893, in the Howard University surgical amphitheater, assisted by Drs. C. B. Purvis, F. J. Shadd, E. A. Balloch, E. F. King, J. F. Francis, and Collins Marshall, after thorough disinfection of the genitalia the operation was performed. The jagged irregular margin of the cervix was drawn down by the vulsellum, and a transverse incision made into the cervix uteri, about half an inch above the margin of the os uteri. The incision was made through the epidermic layer and into the loose areolar cellular tissue lying between the epidemic covering and the body of the uterus. Then by picking up a small quantity of areolar tissue at a time, and dividing it by means of the curved, sharp-pointed scissors used in gynecologic work, the enucleation was performed. This process was continued around the circumference of the neck and body of the uterus, keeping, of course, the points of the scissors closely in contact with the organ, until the layer of epidermis and areolar tissue was gradually peeled upward from the neck and body of the womb. In this process material aid was rendered by the assistant drawing down by means of the vulsellum the neck of the uterus, as the process of enucleation progressed, until the organ was gradually brought down into full view. During the latter part of the operation, a blunt instrument (a retractor) was used to peel off the peritoneum from the anterior and posterior surfaces of the uterus, in order to facilitate its removal. The most difficult part of the operation was the separation of the womb from the dense layer of cellular tissue that immediately surrounds the cervix, at the point immediately over the internal os uteri. The rest of the enucleation was comparatively easy.

As is well known, the bloodvessels of the uterus lie in this loose mesh of areolar or cellular tissue that surrounds the organ, and the great advantage of the operation I have described is that it almost entirely prevents hemorrhage. I did not ligate a single bloodvessel during the operation, nor was I obliged to use torsion, or, in fact, any other of the means that are usually resorted to in surgical operations to check hemorrhage. There was, of course, some oozing of blood, but nothing that could be called a hemorrhage. The operation was a tedious one and occupied forty-eight minutes. I feel quite certain that on other occasions it could be performed in much less time. The latter stage of the operation was very carefully carried out in order to avoid wounding the bladder in front and the rectum behind; neither of these organs sustained any injury during the operation. The atrophied remains of the broad ligaments and Fallopian tubes were dissected off the fundus of the uterus and remained in the cavity of the abdomen after the operation. The last step of the operation was the peeling off of the peritoneal covering from the fundus and body of the uterus, which was successfully accomplished without injury to the peritoneum and without opening the peritoneal cavity. The cavity in the abdomen formerly occupied by the uterus was washed out with weak sterilized carbolic solution, and a tampon of iodoform-gauze, five inches in length and about one inch in diameter, was introduced into the opening made by the operation.

On the evening of the operation, November 22, 1893, at 9 P.M., the temperature was found to be normal, and the pulse 86. On November 23d, the temperature, at 12 M., was 98.8°; the pulse 84. The woman had vomited a number of times during the night; she was given lime-water and milk and cracked ice in small quantities. The temperature in the evening was 98.8°; the pulse 86. Mustard sinapism to the epigastrium was ordered. There was a slight discharge of bloody serum from the wound. On November 24th the temperature at 12 M. was 98.9°; the pulse 86. The woman was much more comfortable, and vomiting had not occurred since the night before. There was a slight discharge of serum tinged with blood from the vagina. As there was no odor from the discharge, it was deemed best to leave the iodoform-gauze tampon in place for another twenty-four hours.

The subsequent history of the case was uneventful. The highest temperature reached was three days after the operation, when it reached 102.8°, but it fell the next day to the normal point.

Vaginal antiseptic injections were used twice a day, and the tampon was finally removed on the fifth day after the operation.

The patient was kept in bed for three weeks after the operation. Her convalescence was slow but steady, and she was finally discharged from the hospital on January 4, 1894, apparently perfectly well.

This operation (enucleating or peeling out the uterus from its peritoneal coverings) is one that, it seems to me, ought to supersede, in cases of carcinoma of the neck of the uterus, every other method of performing vaginal hysterectomy.

It is ridiculously simple in principle and by no means so difficult in practice as it would seem to be. Fortunately for the success of this operation, the uterine arteries lie in the loose mesh of areolar or cellular tissue which immediately surrounds the neck of the uterus, and from thence send their branches transversely into that organ. By introducing the points of the scissors carefully into the cellular tissue surrounding the cervix, it can be gradually snipped off without wounding the main trunks of the vessels, and the smaller branches are torn across and contract in great measure during the process

of dissecting them off. As I have said, I did not find it necessary to ligate a single artery during the operation.

It should be remembered that the advanced age of the patient rendered it a very favorable case for the operation. As the menopause had long been past, the atrophied condition of the Fallopian tubes and broad ligaments rendered them easily removable without the risk of dangerous hemorrhage. If, however, this operation should be performed upon a young woman during the activity of the menstrual function, it is very obvious that the ovarian arteries at least would probably require ligation, and that the cavity of the peritoneum would necessarily be opened with the attempt to sever the attachments of the broad ligaments and appendages.

The ovaries and Fallopian tubes can easily be removed during this operation, by dissecting closely to these structures, and the rent in the peritoneum can be closed with aseptic catgut ligatures. If hemorrhage should occur from bloodvessels during the operations, these vessels can be readily ligated or twisted, as the eversion produced during the enucleation of the uterus brings them readily into view.

The absence of shock and hemorrhage seems to render this a most desirable operation for the removal of the uterus in cases of carcinoma, and it seems to me that if carefully performed, scarcely any mortality should attend it.

INFLUENZA FOLLOWED BY PLEURITIS AND ENDOCARDITIS.

By AUGUSTUS A. ESHNER, M.D.,
ADJUNCT PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC.

The case herewith reported is of interest as illustrating the diversity of complications observed in the course of influenza. It can be truly said that there is scarcely an organ or a structure that has not in one form or another been made to feel the influence of the poison of this remarkable and virulent disease.

J. McG., a laborer, twenty-five years old, presented himself at the Polyclinic in December, 1891, with the symptoms of a mild attack of influenza, which readily yielded to the administration of two grains of quinin with three grains of antipyrin in capsules. Physical examination at this time showed the pulmonary percussion-resonance to be unimpaired and subcrepitant râles to be audible at various parts of the chest, upon both sides, anteriorly and posteriorly. The man was in a reasonable time entirely relieved of his symptoms; but three months later he returned with a history of pain in the left hypochondrium of two weeks' standing, radiating to the shoulders and accompanied by sharp pain shooting down the left arm.

There was present a slight cough, with an occasional sense of chilliness. Upon physical examination dulness upon percussion was found upon the left side of the chest, extending anteriorly from the level of the fourth rib in the nipple line and posteriorly from the level of the spine of the eighth dorsal vertebra to the base of the chest; in this area the breath-sounds could not be heard, and vocal resonance and fremitus could not be elicited. The area of cardiac percussion-dulness was unchanged, although the heart-sounds were less well heard at the apex than at the base. The patient was directed to go to bed, to restrict himself to a dry diet, to apply a cantharidal plaster to the left side of the chest, and take ten grains of potassium iodid three times daily.

A week later the percussion-dulness on the left side was found to have risen to the level of the third rib anteriorly and the fifth dorsal spine posteriorly. The patient was now admitted to the Polyclinic Hospital, and remained for a month. During this time a systolic murmur appeared at the aortic valve, which persisted for some weeks, gradually growing fainter, until it finally disappeared. The temperature was elevated and pursued an irregular course; the patient complained a good deal of pain. The treatment consisted in the administration of alkaline diuretics, hydragogue cathartics, and the application of a blister over the heart. The fluid in the left pleural cavity was gradually absorbed and dense adhesions formed, as indicated by the substitution of dulness on percussion for the previous flatness and the renewed transmission of the respiratory and vocal sounds.

After dismissal from the hospital the patient slowly but progressively improved, and now, after the lapse of two years, is well, except for a syphilitic infection, recently acquired, and for the bone-pains and headache of which the man again presented himself. On physical examination it is found that the left shoulder has sunk to a lower level than the right; a right lateral curvature exists in the dorsal region, and a compensatory left lateral curvature in the lumbar region. The percussion-resonance is impaired over the entire left side of the chest, while the breath-sounds seem distant and the vocal resonance is muffled. The area of cardiac percussion-dulness appears normal, while the action of the heart is quite rhythmic, and its sounds are clear.

Though the case was not under constant and continuous observation, I am convinced that the sequence of events was an attack of influenza, followed by pleural and endocardial inflammation. Influenza is generally admitted to be an infectious disease, and an abundant experience has demonstrated that it is one of those of which one attack rather predisposes to than confers exemption from subsequent attacks, so that it is not impossible that in the case reported there may have been two attacks of influenza, of which the second was complicated by the inflammation of the serous membranes. Clinical testimony is accumulating to show that the serous membranes are particularly prone to suffer from the intoxications resulting in the course of the various infectious diseases.

MEDICAL PROGRESS.

The Inch-and a-half Incision and Week-and-a-half Confinement in Appendicitis.—At the recent meeting of the New York State Medical Society, Dr. Robert T. Morris stated that we had recently learned four principal things relative to appendicitis, and he was now asking the members of the profession to accept a fifth point.

First. Appendicitis is of such common occurrence that every general practitioner has many cases in his *clientèle*.

Second: Multitudinous forms of abdominal inflammation are symptomatic of appendicitis.

Third: Statistics show that late operation does not give much encouragement.

Fourth: Early operation, or operation in the interval between attacks, is an operation with trifling mortality (with none at all in Dr. Morris's experience). There is, however, danger of ventral hernia if a long incision is made.

The fifth point is this: A long incision is not necessary in cases of appendicitis that are operated upon at the outset of the inflammation, or, as a rule, in cases operated on in the interval, and there will be no hernias and no permanent scars if the surgeon will accept as a standard an incision one inch and a half in length, the divided structures of the abdominal wall being united separately with fine catgut. The stump of the appendix is buried with Lembert sutures. The abdominal scar disappears entirely, so that at the end of a few months it cannot be seen. The death-rate has been *nil* in cases in which suppuration was not present, and diagnostic alertness has so increased that it is unusual to find pus. Attention was called to the danger of intussusception of the ileum from the use of sodium carbonate for reversing peristalsis of the bowel. To induce such peristalsis, sodium chlorid is to be preferred.

Although there is strong opposition to the plan of removing an infected appendix just as soon as it is discovered, this opposition must fade away when physicians generally will have learned that appendicitis is an infectious exudative inflammation, which does not subside with the disappearance of the symptoms. Dr. Morris has removed a large number of appendices from patients who felt perfectly well, but who could not obtain life-insurance, or who feared recurrence, having had a previous attack of appendicitis. In all of these cases destructive processes were found in progress. Sometimes there was a slowly progressing necrosis of the lymphoid tissue of the appendix; sometimes tuberculosis or carcinoma was found insidiously beginning at the seat of the old inflammation; sometimes adventitious bands set snares for bowel; and proliferating endarteritis, which must eventually lead to gangrene of the appendix, was common in very mild chronic cases.

Appendices that appear upon macroscopic examination normal, may, upon bacteriologic investigation, prove not to be so. Dr. Morris has removed two or three appendices which were apparently perfectly normal, but the patient's symptoms all disappeared after the operation, and cultural and microscopic examination of these specimens showed that they were dangerously infected, the mucosa and adenoid tissue being in process of destruction by the colon-bacillus.

Dr. Morris stated that when the inch-and-a-half abdominal incision is employed in the removal of infected appendices, patients leave the hospital at the end of a week and a half. If an incision two inches long were made, the patient would not be ready to leave until fourteen days after the operation, and if the incision were from two and one-half to four inches long, eighteen days would be required for repair.

By immediate operation in acute cases was not meant on the following day, but in the following hour.

The Visual Fields in Cases of Hysteria.—As the outcome of an elaborate study, J. K. MITCHELL and G. E. DE SCHWEINITZ (*Journal of Nervous and Mental Diseases*, vol. xix, No. 1, p. 1) arrive at the conclusion that achromatopsia, or loss of color-sense, is not observed in cases of hysteria in the United States, although reversal in the normal sequence of the colors, so that the red field is the largest, is usually present when there is anesthesia. That the disturbance of the color-sense and the anesthesia are, however, not related to one another is proved by the fact that in some cases of universal anesthesia there is no alteration in the visual fields. The green field is, relatively at least, more frequently contracted than the others. When the differentiation between certain types of neurasthenic and hysteric patients is difficult, the presence of disturbance in the color-sense may prove of diagnostic import: it is less likely to be present in the former than in the latter. Its absence is of little significance, as it may not be found in typical cases of hysteria, while it may be present in cases of neurasthenia. It is possible that in the rare cases of hysteric unilateral or general hyperesthesia it will be found that colors are more accurately appreciated than is normal, and that the color-fields are correspondingly enlarged. The violence of the hysteric manifestations bears no relation to the disturbance of color-sense. Some of the following changes, so far as the field of vision is concerned, are likely to be present in cases of hysteria: Simple contraction of the color-fields, with unaffected form-fields; contraction of the fields for both color and form, the green field being relatively more greatly contracted than the others; partial or complete reversal of the normal sequence in which colors are appreciated, most commonly that variety in which the red field is greatest in extent (under these circumstances the color-fields may be normal in extent, sometimes even wider than is normal, or there may be an associated contraction of all of the color-fields); unusual obscuration of portions of the visual field, for example in the form of hemianopsia or greater contraction of the field on one side than on the other, the greater contraction usually being on the same side as the anesthesia.

Carcinoma of the Stomach in the Sequence of a Round Ulcer.—KOCH (*St. Petersburger medicinischer Wochenschrift*, 1893, No. 43, p. 385) has reported the case of a pregnant woman who presented indubitable symptoms of round peptic ulcer of the stomach, which improved with the termination of pregnancy and careful dietetic treatment. With improvement the dietetic restrictions were relaxed and soon hematemesis and other symptoms of gastric ulcer reappeared. In the course of time symptoms of pyloric obstruction developed, which were at first believed to be dependent upon cicatricial contraction at the site of previous ulceration, until, however, it was observed that the reaction of the gastric contents to tests for hydrochloric acid, which had always previously been present, could no longer be elicited, while at the same time the reaction to tests for lactic acid became more marked. Careful palpation failed to demonstrate the presence of a tumor. Operation had been early advised, but was not acquiesced in until the condition of the patient forbade its undertaking, and amid the manifestations of progressive emaciation the patient died of heart-failure. Upon post-mortem examination the stomach

was found to be dilated, its mucous membrane coated with mucus, and presenting a mammillated appearance. At the pyloric extremity the mucous membrane was scarred, and thickened and histologic examination disclosed the presence of cylinder-celled carcinomatous infiltration.

Tubercle-bacilli in House-dust.—MILLER (*British Medical Journal*, No. 1724, p. 62) has reported an instance in which he succeeded in finding tubercle-bacilli in the dust from a house in which tuberculous persons had resided. A lady with her five daughters, four of whom were most of the time at school, took up her residence in a house in which six years previously there had lived a gentleman who had died of pulmonary tuberculosis but a short time after removing from the house. For the next six years the house was occupied by an old lady, who died, but not from pulmonary tuberculosis. Within a year of moving into the dwelling the mother became tuberculous and died at the end of three years. During her illness the eldest daughter displayed symptoms and signs of pulmonary tuberculosis, and left home for six weeks, returning apparently well and remaining well thereafter. A few months after the death of the mother the second daughter, who had not long been away from school, displayed similar symptoms; but she also recovered after leaving home. Several years later the third daughter, soon after leaving school, presented consolidation of the left apex and died within a short time. Stained cover-glass preparations made from dust obtained from the dining-room of the house in which the unfortunate family lived disclosed the presence of tubercle-bacilli in considerable numbers.

THERAPEUTIC NOTES.

The Treatment of Pityriasis Auris.—ALBESPY (*La Semaine Médicale; Wiener med. Presse*, 1894, No. 2, p. 67) describes pityriasis auris as a desquamating dermatitis of the external ear, attended with itching, tinnitus, impairment of hearing, a sense of heat, and sometimes facial neuralgia. The affection does not, as a rule, appear before the twentieth year of life, and usually involves the ear by extension from the hairy head. The treatment consists in pulling out or cutting off the hairs at the entrance of the external auditory canal and removal of the scales by irrigation with a tepid solution of boric acid, followed by the introduction deep into the auditory canal of a cotton tampon saturated with a 5 per cent. solution of argentic nitrate, which is permitted to remain for twenty-four hours. This procedure is repeated until desquamation no longer occurs and the walls of the canal have become smooth and soft. Now, tampons saturated with the following mixture are to be employed:

℞.—Acid. salicylic. . . . . ʒjss.
Balsam. canad. . . . . ʒss.
Collodion. . . . . ʒj.—M.
S.—To be used renewed every four or five days.

The treatment is concluded by the insufflation of air once or oftener. The general condition must not be ignored and arsenic is to be administered.

The Treatment of Rupture of the Uterus.—From an analysis of reports of 230 cases of rupture of the uterus, MERZ (*Archiv f. Gynäkologie*, B. xlv, H. 2, p. 181) comes to the conclusion that when the lower extremities and the pelvis of the fetus have entered the abdominal cavity of the mother, the head remaining in or over the pelvis, delivery should be accomplished through the natural channels by means of forceps or perforation and craniotractor. If the head, or entire body of the fetus, has entered the abdominal cavity, version and other obstetric procedures should not be undertaken; but, to avoid enlarging the perforation of the uterus, celiotomy should be immediately undertaken, and the fetus delivered through the abdominal incision; and the perforation should at once be sutured. If delivery has been accomplished through the natural channels, celiotomy and suture of the perforation, under moderately favorable conditions should be practised at once. If the conditions forbid the performance of celiotomy, drainage with iodoform-gauze should be provided for, without previous irrigation. If the uterus is badly lacerated, or if septic endometritis has developed, the removal of the uterus should be practised.

The Treatment of Erysipelas with Chlorphenols and Bromphenols.—TCHOURILOW (*La Semaine Médicale*, 1894, No. 2) has employed topical applications of 1, 2, and 3 per cent. ointments of orthochlorphenol, parachlorphenol, and orthobromphenol in the treatment of erysipelas, with satisfactory results. The ointment is carefully rubbed into the involved area for about a minute twice a day. The friction is followed by tingling, sometimes by a sense of painful pricking, which disappears in the course of two or three minutes. Of 25 cases thus treated a cure ensued on the second day in 6; on the third day in 8; on the fourth day in 3; on the sixth day in 2; on the seventh day in 4; and on the eighth day in 2. It is further believed that good results could be obtained by subcutaneous injection of the same agents in aqueous solution.

For Pulmonary Tuberculosis STRIZOWER (*Wiener klin Wochenschr.*, 1894, No. 3, p. 43) recommends inunctions of mercurial ointment. A half-dram of the ointment is rubbed into the skin daily, and a warm bath is taken after every fourth inunction. It is not claimed that the treatment is infallible or universally applicable. In cases in which it fails to do good, however, it at least does no harm.

For Coryza.—

℞.—Betol . . . . . ʒijss.
Menthol . . . . . gr. xv.
Cocain hydrochlorate . . . gr. ix.
Powdered roasted coffee . . ʒjss.
Mix and use as a snuff.

GRELLETY, *Sem. Méd.*, No. 72.

For Gastric Ulcer.—

℞.—Bismuthi subnitrat. . . . ʒjss.
Chloroformi . . . . . f ʒss.
Aquæ . . . . . f ʒx.—M.
S.—Two tablespoonfuls, from three to six times daily.

STEPP, *Wiener med. Presse*, No. 51.

THE "CONTAGIOUSNESS" OF LEPROSY.

As we have already had occasion to point out, some confusion still exists as to the precise interpretation of the terms "infectious" and "contagious." Modern usage has very much limited the application of the qualification "contagious," and for practical purposes the word might well be permitted to fall into disuse. In its simplest, and at the same time strictest, sense an infectious disease is one that is transmissible or communicable from person to person, or from animal to animal, directly or indirectly. The channel of communication may not always be evident. The most common media, however, are the air, water, milk, food, clothing, and the fluids or tissues of the sick. Sometimes a third person, who may himself escape, may convey disease from one person to another.

These facts imply that an infectious disease must be dependent upon some definite and unvarying agency that is capable of generating the specific disease and no other, and that it is most likely capable of perpetuation and propagation; and also that the existence of any one instance of the given disease bespeaks the occurrence of preëxisting cases. The degree of infectiousness, the virulence, the intensity, the activity of the causative agency, on the one hand, and the attitude of the exposed individual, his receptivity or his resistance, the suitableness or unsuitableness of the soil, the directness or indirectness of the transmission, on the other hand, are different and distinct, though not unimportant, matters. It thus comes about that certain diseases are intensely infectious, mere exposure in the presence of the sick sufficing for their transmission, *e. g.*, typhus, smallpox, yellow-fever; in other instances, the source of infection is found to reside in some definite exhalation or excretion, as, for instance, in the squamæ of scarlatina or the membrane of diphtheria; in still other instances, this source resides in the intestinal evacuations, as in enteric fever, in cholera, in amebic dysentery; or the infectious matter is contained in the sputum, as in pulmonary tuberculosis, in pneumonia; finally, in some diseases, of which syphilis and leprosy are types, it is essential that, under ordinary conditions, the contact between the sick and the well must be direct and immediate in order that infection may take place. It is likely that both leprosy and syphilis are not inoculable upon the unbroken surface of the body, and it is possible that even when wounds or abrasions exist inoculation may not take place, in virtue of the power of the individual organism to throw off the noxious agent, in the same way that all persons exposed, for instance, to the infection of scarlatina do not become scarlatinous, and all who drink water contaminated with discharges from cases of enteric fever or cholera do not develop enteric fever or cholera.

Now we think it will be conceded that all of the diseases that we have named are infectious, *i. e.*, capable of transmission—diseases whose causes are susceptible of perpetuation and propagation. The distinction, however, of calling some of these—for instance, smallpox, scarlatina, diphtheria, typhus—contagious because the transmissibility is the greater and the more subtle, and to exclude from this category others—for instance, tuberculosis, leprosy, syphilis—whose channels of communication are more obvious, though less direct, would seem to be purely arbitrary, to say the least. Contagious diseases are necessarily infectious, and conversely infectious diseases are contagious, though in varying degree. Thus all essential distinction between contagious and infectious falls, and if the term "contagious" is at all to be retained, it should be with the knowledge that it applies but to a form of infection.

With this conception of the two words, which we

think the present state of knowledge justifies, there is little difficulty in harmonizing the views of those who take opposite sides in the discussion as to the contagiousness or non-contagiousness of such diseases as tuberculosis and leprosy in particular. Surely the time has passed when any will seriously question the infectiousness of both of these diseases. The general consensus of opinion the world over is that each is etiologically dependent upon a specific microörganism (though, of course, it is not pretended that the microörganism is the sole etiologic factor); but even the scattering remnant that may have any doubts upon this point will hardly deny the communicability of the diseases. The question of heredity is to-day believed to play a much less important part in the development of tuberculosis and leprosy than was formerly believed. It is probable that any influence that heredity exerts is by virtue of the transmission of cytologic, formative, and developmental peculiarities, or better, tendencies, which make the individual unduly susceptible, so that he falls an easy prey to disease. Cases of congenital tuberculosis or leprosy are rare, and not above suspicion.

Investigation has shown that there are certain foci from which leprosy spreads by the more or less intimate contact of the unaffected with the sick; and experience has also taught that when segregation has been practised, either voluntarily or compulsorily, leprosy has diminished. The disease is most common and shows a tendency to increase only among those whose habits of life necessitate the sleeping together, the eating from the same dishes, the use of the same utensils, the wearing of the same clothing on the part of both sick and well. In the case of tuberculosis it is granted that the hygienic surroundings have a most important influence in predisposing to the disease; but this influence is much slighter, though not entirely without weight, in the etiology of leprosy. Nor, as has been thought, has the character of the food, and particularly the use of fish or the absence of salt, aught to do with the development of leprosy, or the geologic or geographic or climatic conditions, as the recent report of the Indian Leprosy Commission goes to show. In so far as poverty implies overcrowding and bad habits, and carelessness and lack of cleanliness in all relations, in so far does poverty play a part in the causation of leprosy. It is not impossible that leprosy, like syphilis, may be transmitted by means of the use of humanized lymph from infected persons in the practice of vaccination.

There may be some doubt as to the practicability of isolation in the management of cases of tuberculosis, but there can be no such doubt in the case of leprosy, and actual experience has demonstrated the wisdom of this mode of procedure. We would go so far, however, as to say that it would be wise to pursue a parallel line of action in the management of tuberculosis, to the extent of providing institutions in which those could be suitably cared for who were either unable to properly care for themselves, or by choice sought the advantages of isolation and such treatment as can only be carried out in specially equipped institutions. In this instance the segregation would have to be volitional; in the case of leprosy it should be compulsory. As, in the case of tuberculosis of the lungs, the sputum constitutes the most common medium of transmission, particular attention should be directed to its sterilization on the one hand, and to prevention of its dissemination on the other hand. Finally, it seems hardly necessary to add that marriage among the tuberculous and leprous should not be sanctioned.

THE MENOPAUSE OR PRESBYOPIA?

ONE of the most frequent illustrations of false logic comes from the superstition among the laity that in a woman's life the years of the menopause are peculiarly and remarkably distressful years. The noteworthy article of DR. GOODELL reproduced in THE MEDICAL NEWS of January 6th illustrates the profound responsibility that rests upon the profession in reference to the mistaking as genital in origin many phenomena due to other causes. It is doubtless true that the popular belief in all sorts of woes coming upon woman from the age of forty to fifty, as a result of the "change in life," is in great part due to the easy acquiescence of the physician in the somewhat morbid popular logic. In olden times it was, generally speaking, a happy way to avoid both responsibility and the search for real causes of sin, by charging it to the devil, and likewise the physiologic evil of women has been all too readily charged to the mysterious uterus. Every physician knows the perfectly self-satisfied air with which ladies explain all the ills, real or imagined, that occur within five years before or after the menopause, as most certainly due to this mere negation of function. They are quite indig-

nant if a doubt is hazarded about the matter, and not infrequently the doubt is held to be proof positive to the reckless diagnostician that the doubter is a very poor sort of a doctor indeed who is not fully alive to the self-evident truth.

But there are lots of other things that occur in the organism of woman at about the age of forty-five, besides the cessation of certain genital functions. Let us look at one of them—presbyopia. If astigmatism, anisometropia, or hyperopia have preëxisted, the beginning of presbyopic troubles occurs earlier than in the emmetropic, and the reflex phenomena are more marked, proceeding even to the production of violent suffering. The earliness of oncoming of presbyopic reflexes, and the degree of their intensity is in direct proportion to the refractive error. The more likely these errors are to produce pathologic reflexes, the more certain are they to produce them to a marked extent about the age of forty. Every oculist has had daily experience of these facts, and he further knows how speedily the reflexes disappear when proper ametropic and presbyopic correction has been provided.

It is, therefore, a natural but none the less a reprehensible error, lay or medical, that headache, dizziness, and the thousandfold manifestations of ocular reflexes should be mistaken for menopausal reflexes. And it is especially significant—this further fact, known to every oculist—that with the presbyopia uncorrected, the struggle against the presbyopic paresis often continues with much suffering until finally years or glasses bring relief.

Now whether the relief comes from established or completed presbyopia and the resultant cessation of reflexes, or whether it comes from glasses, an easy and lame logic is most likely to jump to the conclusion that at last the organism has conquered the huge difficulty of menstrual cessation. One wonders how the simple cessation of a function of an organ that, as it were, is only semi-attached to the organism, a function that comes on at maturity and ceases when life is about half over—a function that one might call parasitic—one wonders, we say, how it is that its simple stopping could ever have been credited with such a deal of mischief. In man a far stronger function, one that in a sense begins earlier and certainly lasts much longer, ends as unnoticed and uneventfully as can be.

It is not to be understood that we would deny all abnormal phenomena as due directly to the menopause. The "hot and cold flushes," etc., and in rarer cases the most pronounced examples of painful reflexes, may occur. We protest only against the wholesale ascription of the abnormal phenomena that occur at and about this period of life to the menopause, and urge that thousands of errors of diagnosis and so of treatment (or failure of treatment) have been due to the error of logic described. At this time of life—and although true of men this is especially true of women—the oncoming of presbyopia is often intensified by preëxisting ametropia, and produces reflexes, astonishingly various in nature and location, that are wrongfully ascribed to the genital disorder. It therefore behooves the physician to be on his guard against this mistake, and to consider if his patients suffering from such symptoms may not find comfort with relief of the ocular strain. The disinclination of the lay mind, and sadly often of the professional mind, to see or to acknowledge the frequency and severity of the reflex symptoms due to eye-strain, coöperates with the false logic of which we have spoken, and hence a large number of women go on suffering for years, the mistaken diagnosis even proceeding to operations on the genital organs. We wished in this writing to simply add a supplement to the altogether admirable article of Dr. Goodell concerning the *great medical error of the day*, the purport of which is that the specific source of many of the general nervous or extra-genitally located symptoms that are so commonly and so mistakenly ascribed to a genital origin, do in fact lie in the eye, and at or about the age of forty are especially due to presbyopia.

EDITORIAL COMMENTS.

Minority Rule in a Democratic Form of Government.—Concerning the defeat of the attempt to secure the enactment of a bill for establishing a Medical Examining Board in the State of Georgia, the following noteworthy comments and admissions are made by the *Medical Century* (Homeopathic):

"*It is a fact that the Homeopathic profession is opposed to the examining board plan of control. It is the plan that has crushed us out of existence almost, in Germany and several other foreign governments, and it is the plan that retards our growth and development in Europe, in Canada, and in those States of the Union as have thus far adopted it.* Yet we find here and there a willingness on the part of our forces to accept the measure, largely on the grounds that it cannot be avoided, and that we had better, therefore, accept our part of it, no matter how little or how much that may be. *In New York, Maryland, and one or two other States, we have contended for separate boards, and have won*

them, with the result that our interests have been shown to have suffered the same, almost, as though but a single board had existed. In Minnesota, and one or two other States, our colleges have allowed themselves to be entrapped into consenting to a minority representation, with the result that they are about as well off as in those States having three boards, all being in much worse condition in so far as growth in numbers and other developings are concerned than in most States having no boards, but good registration laws instead. And it is a fact that in every State having a board law a good minority of our school, if, indeed, not a good majority, have yielded their convictions against the board plan of control to the thought that boards it must be, and, therefore, we had better get what we can out of it.

"The victory in Georgia shows that this is sheer weakness. Dr. Orme and a few colleagues, together with such opposition as could be brought to bear from the eclectic school, has been able to defeat a bill in a State in which Allopathy is unusually strong, and Homeopathy unusually weak. Likewise the homeopaths of Louisiana have recently defeated a similar measure in their State, whereas they number less than a score and a half against over 1500 allopaths. And in Texas our forces, numbering less than a hundred, have defeated the old school three different times, the latter numbering above 4000 strong.

"These victories in the Southern States, where homeopathy is in almost a hopeless minority, while the old school is securely intrenched with all the prestige of numbers, political preferment and position, and financial and social standing in high degree, should teach us a lesson of courage and determination not to allow the older sect to rule in this matter. It has proclaimed from the house-tops that by the examining board plan of control it will crush out all opposition to 'regular' medicine, and it at once becomes our duty, and should become our pleasure, to oppose to the death all medical legislation looking to the formation of examining boards, no matter how constituted."

It therefore appears that neither the homeopaths nor physicians desire the ignoble compromise distasteful to both, but accepted by both, because neither can have what it wishes. This reminds us of the story of the rich man and his wife, who quarrelled for years about the disposal of their fortune, each wishing to will it to a favorite heir. They finally compromised by leaving it to a distant relative heartily detested by both.

What an amount of pusillanimity and pigheadedness about this whole affair! Why do the scientific physicians of the country not demand that the first principle of all civilized government, rule of the majority, shall obtain in medical legislation? Why, in the name of common sense and decency, all this disgraceful dodging and dickering?

The Etiology of Gastric Ulcer.—Many causes have been assigned for the production of ulcer of the stomach, but no one is sufficient to explain the occurrence in all cases. It is, however, pretty generally agreed that the predisposing condition is some impairment of the vitality of the cellular structures, whether as a result of preceding inflammation, of traumatism, of chemic influences from without, of interference with the circulation, of the presence of infectious or toxic elements in the blood, of the breaking down of neoplasms, or perhaps of some nervous influence, and that the exciting influence consists in an altered relation between the alkalinity of the blood and the acidity of the gastric juice. It is well known that the condition is most common in anemic young women. It may occur in the course of other forms of profound deterioration of blood, such as scurvy and purpura. It often develops in the course of carcinoma of the stomach, and has been observed in the sequence of enteric fever. Some investigators have found streptococci in thrombi that have formed in the gastric veins in cases of puerperal infection. Gastric ulceration has also been induced experimentally by the intravascular injection of pus, by the intra-peritoneal injection of staphylococci, and by the intra-gastric and intra-peritoneal injection of bacilli found in some cases of dysentery.

An interesting contribution to this subject is made by two French observers, Enriquez and Hallion (*La Semaine Médicale*, No. 73, 1893, p. 579) in a paper presented at a recent meeting of the Société de Biologie, of Paris, who reported that in a series of observations they had found that subcutaneous injections of the toxin of diphtheria in guinea-pigs and dogs were followed by ulceration of the stomach. Two dogs thus treated presented symptoms of gastro-intestinal catarrh, with bloody stools, dying after the lapse of eight and fourteen days, respectively. Upon post-mortem examination gastric and intestinal ecchymoses were found in one case, and ecchymoses and ulceration of the stomach in the other. Eight guinea-pigs lived for periods varying from two to fifteen days after the injection, and upon post-mortem examination lesions of the stomach were found in seven of the animals. The morbid changes were seated almost exclusively in the pyloric region, and upon the lesser curvature. They consisted in multiple ulcerations, some small and irregularly rounded; others larger and more irregular in outline. Besides these areas of ulceration there were present grayish sphacelated patches that were easily detached. On histologic examination the sphacelated areas were found to be limited to the thickness of the mucous membrane. The deeper layers of the mucosa were congested and infiltrated with round cells. Similar changes were also found in the structures adjacent to the ulcerated areas. In these situations the submucosa was thickened, and displayed manifest endarteritis. The changes in the mucous membrane corresponded accurately to those in the submucosa, and especially to the distribution of the vascular lesion. It seems difficult to escape the inference that in the experiments detailed a relation existed between the toxic injections and the occurrence of the arteritis, with the development of ulceration in the area supplied by the affected vessels; and likewise the analogy between the ulceration thus artificially induced and the condition as it is encountered in man.

Should Physicians Charge Each Other for Medical Services?—In view of the almost universal custom of physicians, as well as of the tradition of the profession, the question would seem to be almost insulting. Nevertheless there are a number of physicians who would answer the question affirmatively, and others who would not say No with quite the emphasis to be expected. The question was lately asked of a prominent and highly respected physician, and his answer was that, while no honorable

physician, without demand, would name a charge or send a bill to a brother physician, it is growing more and more customary for the recipient of the service to demand the bill. There is, perhaps, something to be said upon this side of the question. In default of a money-payment, the grateful patient will naturally make his physician some gift, but he finds it difficult to select a suitable present; it makes him, apparently, a useless trouble, and he keeps thinking that his physician might as well take the money and spend it more to his own liking. In obstetric cases, in prolonged illness, or other work wearying, or expensive, whether to life or pocketbook, certainly no physician would permit his benefactor to go without some more substantial reward than the most sincere gratitude. The result of the tendency to put the service on a financial basis would, however, lead easily to abuse, and would likely soon destroy that largeness and lovableness of spirit, that mutual helpfulness and *esprit de corps* that has been one of the most delightful and enheartening characteristics of the medical guild. Such a cloud over the medical landscape would give it a very different tone from what it has heretofore shown, and, we are happy to say, which it still exhibits. Nothing so robs a man of respect, nothing sooner surrounds him with an atmosphere of concealed contempt, nothing more speedily deprives him of professional skill or usefulness, than the basing of every act on the hidden thought of "How much money can I get out of it?" A surgeon once performed an operation on a physician's wife, and took occasion during convalescence to ridicule the offering of a small gratuity sent him for a similar service by another physician, as well as otherwise hinting the money-value of his work, and this despite the history of many "reference-cases" from the lady's husband to the surgeon. However large the fee gotten by such means, it was, as we all know, stupidly poor policy and worse principle. The very air about such a man shrinks from him.

Medical Advice at the Rate of Two per Cent. a Ton!—A prominent physician of one of our Southern seaports writes us of a deplorable custom existing there, and it is one we doubt not that is becoming common at other ports. Printed notices or engraved cards are distributed by competing physicians to the captains of incoming vessels, setting forth the doctor's own fitness and scientific abilities, and soliciting the patronage of the crew while the vessel remains in port. The rates are "2 per cent. a ton." That is, for a vessel of 1500 tons, the entire crew may have the unexcelled services of this unexcelled therapeutist and surgeon for $30 until the ship again departs. It matters not whether the stay in port is one week or one year, and whether one man or twenty are sick or wounded. The business is strictly wholesale.

But these are the days of great undertakings, of syndicates, of the systematic marketing of virtue, of quotations by the "ticker" upon medical honor, nostrum-puffs, and professional skill. Hence we may doubtless look for a proper extension of the plan by some enterprising company-former, or "promoter," who shall concoct a syndicate and be able to offer wonderfully low rates to all vessels and for all the seaports of the United States, the contracts to extend for a year, or ten years, or perhaps for eternity, "at the option of the party of the second part."

Ethical Advance.—It is with more than ordinary gratification that we note the following announcement in the January number of the *Canadian Practitioner*, one of the most prepossessing monthlies that come to our hands: "We have much pleasure in announcing that in the future our eighty pages of ordinary reading matter will not be marred by the presence of 'inserts' or fly-leaves of any description pertaining to advertisements, nor will they contain what are called reading notices of articles advertised. Our advertisements will appear in the place allotted to them, and none of an objectionable character will be allowed to appear."

An Anatomist's Anomaly Blank, designed for the use of dissectors in recording any noteworthy anomaly that may be found, is a praiseworthy device of Dr. A. Hewson, of Philadelphia. The sheet has proper spaces for the student's name, the principal normal physical characteristics of the subject, and for anomalies of each of the principal organs or classes of tissues, in proper order and sequence. The proper recording of the anatomic peculiarities occurring in the thousands of dissections made in the country would eventually result in interesting and valuable scientific lessons.

A Physician Can Testify as to the Effect of Wounds Merely Described to Him.—When other witnesses have furnished descriptions, say of wounds, the Supreme Court of Georgia holds, in Von Pollnitz *vs.* State, that a practising physician is a competent witness to form and express an opinion, as an expert, touching the probable effect of such wounds. Under such circumstances the examination should be conducted on a hypothetic rather than on the actual case. No objection being raised to the latter course at the time, it will be sustained.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Special Meeting, held January 12, 1894,

THE PRESIDENT, S. WEIR MITCHELL, IN THE CHAIR,

To consider the Proposed Action of the Board of Health in Reference to the Registration of Tuberculosis.

THE Council, to which the resolution and amendment with reference to the proposed action of the Board of Health concerning tuberculosis were referred, offered the following resolution to the College:

Resolved, That the College of Physicians believes that the attempt to register consumptives and to treat them as the subjects of contagious disease would be adding hardship to the lives of these unfortunates, stamping them as the outcasts of society. In view of the chronic character of the malady, it could not lead to any measures of real value not otherwise attainable.

That strict attention on the part of physicians in charge of the individual cases, insisting on the disinfection of the sputum and of the rooms, on adequate ventilation, and on the separation of the sick from the well

as far as possible, will meet the requirements of the situation so far as they practically can be met, and better than any rules that, for diseases so chronic, can be carried out by a Board of Health.

That the College of Physicians respectfully requests that no official action be taken in the matter by the Board of Health, except the insisting on disinfection of rooms in which consumptives have lived and died in instances in which such procedure is not likely to have been adopted under the direction of the attending physician.

DR. OWEN J. WISTER: When I offered my resolution at the December meeting of the College it was objected by those who are in favor of registration of cases of consumption that nothing was intended beyond registration in order that medical literature of a kind to warn persons of danger might be sent to their houses. In a paper read before the Pan-American Medical Congress on "Tuberculosis," and published in THE MEDICAL NEWS of October 21, 1893, there is a good deal more in reserve which is insisted upon.

Registration, in the first place, is meant to include the residences of all persons affected with pulmonary tuberculosis, and even if the place of residence is temporarily changed it must be by and with the consent and knowledge of the Board of Health.

As to the literature, so called, I think that is of doubtful desirability. Those who spent the summer of 1892 in town, when there was a cholera-scare, will remember that there was a great deal of this sort of literature—the papers reeked with it. The evening papers published articles of such a sensational character that the Health Officer was lashed into such a state of hysterics as to propose a quarantine against New York, under the act of Legislature which makes such a proceeding lawful when a contagious disease is "raging in a neighboring city." The "rage" in this case amounted to four cases in a month in a population of a million. This proposition, however, was not adopted. But while the Board of Health was thrown into spasms of terror, there was enough that was ludicrous in this literature to throw the community into spasms of laughter, and we had a rather cheerful summer. It cannot be hoped that this view will always be taken when, instead of a scare of two or three weeks, it will last ten or fifteen years, while from forty to fifty are dying a week. It is then possible that this literature may lash the whole community into panic, and that instead of regarding the unfortunate victims of consumption as objects of compassion they will be looked upon as fountains of peripatetic danger, and a feeling of hostility to them will arise. This may last for years, for during the whole period of softening they are regarded as sources of danger. In fact, they are to be treated as criminals guilty of consumption. As I said before, their residences, however temporary, are to be disinfected, and their miserable lives are to be rendered more wretched by being haunted by the familiars of the inquisition. It is asserted that if these radical measures are carried out tuberculosis will be eradicated in a few years; of that, it is said, there is no doubt. Now, no other contagious disease has ever been extinguished, even with the added protection of vaccination in smallpox. Those of us who are not in the intimate confidence of Nature find it difficult to understand how an hereditary disease can be eradicated by measures which only limit its spread by contagion; and if it is not hereditary, whence come those forms of tuberculosis other than pulmonary? It cannot be pretended that babies, a year or two old, get tuberculous meningitis by contagion; nor can white swelling, or suppurating glands, or the many other exhibitions of scrofula come from contagion. I think very few of us will concur in this sanguine expectation. There are several other suggestions—one is likely to be very popular: it is that all persons working in factories and the like who are affected with pulmonary tuberculosis, in the softening stage, shall be withdrawn and, when necessary, supported by pensions. In this country we have had a large experience of pensions; pensions have bankrupted the treasury of the United States. It is easy to believe that people unwilling to work could get the necessary certificate from some twopenny doctor and be supported by the State. As to the more serious part of the matter, the treating of persons so unfortunate as to have pulmonary tuberculosis as criminals guilty of consumption is something so frightful that I implore the College to interpose its remonstrance against such an outrage on common sense and common humanity.

DR. L. F. FLICK: Together with other Fellows, I would like to bring up the entire subject for discussion, and without wishing to find fault with Council in referring back the resolution in amended form, I should like to offer a substitute, which will bring up both registration and special hospitals for the treatment of the consumptive poor. The substitute is as follows:

Whereas, Tuberculosis is now known to be a contagious disease; and

Whereas, The methods by which the disease is conveyed from the sick to the well are now clearly understood; and

Whereas, It has been shown that the room which is occupied by a consumptive during the infectious period of the disease, and the furniture and the bedclothing which have been used by him, become infected and are liable to convey the disease to others who may occupy or use them subsequently; and

Whereas, Tuberculosis, owing to its long duration, cripples the bread-earning capacity of the family, when it occurs among the poor, to such an extent that the want and hardships which follow in its wake prepare the healthy members of the family for the disease; therefore be it

Resolved, That we recommend to the Board of Health of the City of Philadelphia the registration and disinfection of houses which have been infected by tuberculosis;

Resolved, That we recommend to the City Councils of the City of Philadelphia the establishment of a Municipal Hospital for the treatment of persons suffering from tuberculosis.

The question of contagion seems to be admitted, and can, therefore, be eliminated from the discussion. I will then take up the question of prevention.

In reply to what has been said by Dr. Wister, I may state that the paper from which he quoted was a scientific paper covering the entire subject. He ought to have told you that the author pleads in that paper only for a beginning in preventive measures.

The contagion of tuberculosis being admitted, what measures are necessary for its prevention? The careful investigation of this subject from many points of view by Dr. Cornet, Dr. DeForest, and myself, show beyond doubt that there is a local infection—that the consumptive in his home is bound in his ordinary daily life to infect his room, the furniture, and the bedclothing. The experiments made by Cornet illustrating this subject are most elaborate. They covered a period of two years, during which time he perseveringly followed out his line of research. He examined the dust gathered from the floor, the walls of the room, the bedposts, and the bedclothing of persons in advanced stages of consumption confined to their beds. He found by inoculation with this dust that he was able to produce tuberculosis. He found, moreover, that when a patient was sufficiently intelligent and obedient to follow the instructions to always spit in the sputum-cup and never into a handkerchief or on the floor, inoculation with the dust produced no effect; but when the patient occasionally spat into a handkerchief, or into a nook in the room, inoculation with dust from the surroundings of these places was effective. He was able to demonstrate that in proportion to the obedience and cleanliness of the patient the extent of the infected environment decreased. When the patient was cleanly and took ordinary precautions, but not absolute precautions, the infection extended to only a limited space, possibly four or five feet. When the patient was uncleanly and spat indiscriminately, not only the bedposts and the floor, but also the walls, were capable of conveying the infection. The clinical investigations which I made in this city, and the clinical investigations made by Dr. DeForest in New Haven, corroborate these results in such a way that their meaning cannot be misunderstood.

The evidence of infection and retained infection of houses, together with the demonstrations made by Cornet, can point to only one conclusion, and that is that the houses which have been inhabited by a consumptive for a given period will retain the infection and convey it to others. I have investigated quite a number of cases which illustrate the same point. I have knowledge of a telegraph office in Maryland in which five consecutive operators contracted tuberculosis and died. The results in these five cases were so striking that people became superstitious in regard to the office. I have been informed by a person who saw the office that the consumptives spat around the office and that it was lined with tuberculous sputa. I have been able in this city to trace a great many cases in which persons innocently moved into houses, unsuspicious of any infection and in which within six months a member of the family who was healthy before has taken the disease, and this case has been followed by others.

Dr. DeForest mentions a very striking result of his investigations in New Haven. He investigated the histories of 100 cases coming to the medical clinic of the city and found that 52 were living in infected houses. In 1888 I carefully examined the deaths that occurred in the Fifth Ward during that year. There were 83 *bona fide* deaths from consumption. Although out of the 3500 houses only 650 were infected; two-thirds of these cases occurred in these infected houses. Of the remaining third a large number had lived in infected houses and had changed their residences, so that apparently more than two-thirds of the cases in which death occurred in 1888 had contracted the disease while living in infected houses.

If the facts I have related are true, how is it possible to institute any practical preventive measures without registration? The education that is spoken of in the resolutions offered by Council will not accomplish much. Cornet has shown that even when the patient has carried out most of the instructions the immediate surroundings are infected. As you are well aware, among the very poor there is no nursing. The consumptive is apt to lie on a bench in the kitchen—a small room, perhaps eight by twelve feet. He has to wait on himself and probably spits all over. Under such circumstances he is bound to infect the room, and it has been shown that the disinfection of such a room does not consist in burning sulfur, but special methods are required. One of the most efficient methods is rubbing down the walls with dry bread and then washing with carbolic acid or some other powerful germicide. The furniture and the bedding also require disinfection. You well know that the houses in which the poor live are owned by men who try to get as much money as possible out of them. The owners will not disinfect these houses if they can avoid it. It is only by the authority of the government that this disinfection can be accomplished.

Now, is the profession ready to step forward and say: "We will make an earnest effort to stamp out tuberculosis?" The profession throughout the country has said that it will. The American Public Health Association, during its session in Chicago, adopted resolutions asking that registration should be practised. The Section on Hygiene of the Pan-American Medical Congress adopted similar resolutions. The Congress of Tuberculosis, in Paris, in 1888, passed resolutions asking that tuberculosis be recognized as a contagious disease, and in 1891 passed a resolution asking that disinfection be practised.

Will disinfection have any effect? It will. I should like to cite one illustration: As far as I know, Berlin is the only city that has taken scientific precautions against tuberculosis. The result is most encouraging. In the city of Berlin there has been a marked reduction in tuberculosis from 1884 to 1891, the most rapid reduction of any city of which I can obtain statistics. In Philadelphia there has been a reduction. In London there has been a vast reduction since the establishment of consumptive hospitals fifty years ago. In Berlin there has been the most rapid reduction; from 1884 to 1891 there has been a reduction of 0.644 per 1000. In 1884 the mortality in Berlin was 3.455 per 1000 and in 1891 2.811 per 1000. In Philadelphia, where we have been priding ourselves on the reduction, there has been in ten years only a reduction of 0.623 per 1000. Whether or not registration is being enforced in Berlin I do not know. I have been told by private parties that it is. Contrasting the reduction in Berlin with the reports from other cities, we find that the mortality in Paris was about the same in 1890 as thirty years before—4.574 per 1000.

Whether or not France will succeed in establishing preventive measures is yet to be known. I have had no definite information on the subject.

As to the sentiment on this question, it is all on the side of registration. I grant that it may be hard for wealthy people to be recorded as suffering from tuberculosis, but this is a disease of the poor; the vast majority of consumptives are very poor, and the necessities of the poor so demand registration that they should outweigh the sensitiveness of the rich. But the sensitiveness of anyone can be overcome by the suggestion embodied in the resolution I offered, a suggestion which was made to me by Dr. James C. Wilson—that is, instead of registering the individual to register the infected house. It would then not be necessary to register tuberculosis among the wealthy, as only houses that had been infected would have to be registered. When infection can be prevented by proper sanitary measures there would be no occasion for registration. This would enable us to register those houses that need to be disinfected.

The best place to study this subject is among the poor. It is there that I have learned my lessons. I am satisfied that every man here will reach my conclusions if he will go among the very poor and study this question at the bedside, and see how, one by one, these people die from the disease because they are unable to protect themselves and because in the endeavor to protect and supply medicine to the stricken one the healthy fall victims to the disease. It is these that need aid. The College of Physicians should now take a firm stand and do something in aid of these people. It is not necessary to do everything at once. Let us make a beginning. Experiments have been made; let us now come to action. It is not fair to the public that the medical profession, with the knowledge it possesses, should do nothing. The laity cannot act because it has not the knowledge. If we who have the knowledge do nothing we are certainly responsible for the deaths of those who otherwise might be saved.

DR. J. M. DA COSTA: Let me say in the first place, that I thoroughly admire the enthusiasm which Dr. Flick has for years brought to the study of this question. I think that the way in which he has gone about this work is in every respect most commendable, and in its spirit and scope this is one of the best series of observations with which I am acquainted. If I differ with him it is rather in the conclusions than with reference to his mode of investigation and his aims.

When we speak of contagion in consumption, we cannot mean that it is markedly contagious. There is no proof that it is. It is not contagious like typhus fever, or smallpox, or scarlet fever, or diphtheria. It is only slightly contagious. It is, indeed, so slightly contagious that some of our best thinkers, with the largest fields of observation, notwithstanding the evidence that has been adduced, still hold that it is not contagious at all. For instance, if we take the opinion of a man so long connected with the Brompton Hospital as Dr. Williams, we find in the last edition of his work on *Pulmonary Consumption*, that he maintains that no more deaths from consumption occurred in the attendants of the Brompton Hospital than occurred among the same number in ordinary life. The evidence of Dr. Andrew, of the Victoria Park Hospital, is in the same direction. When we look at the conclusions of these men and at those of Wilson Fox and many others, it is going too far to assume that the whole profession admits the disease to be contagious.

That it is moderately so, and that it can be communicated under exceptional circumstances, I firmly believe; but that we should regard it as a very contagious disease and take all the precautions that we do in such diseases, I deny. If it be contagious, it is contagious, as everyone admits, chiefly through the sputum. Is it to be understood that an inspector from the Board of Health is to come daily to take care of the sputum-cup? Is not the intelligent physician the proper health-officer? Is not what he says sufficient, and can he not advise and enforce the destruction or the disinfection of the sputum as well as any public officer? Finding bacilli in the bedclothes and on the bedstead, and destroying them, will not eradicate consumption. Tubercle-bacilli are widely diffused. They are in the dust of the air we breathe, blown about from the dried sputum of consumptives in the street. They have been demonstrated to exist on the fruit sold in our markets; they are in milk. They may, indeed, be said to be everywhere; and not only in the homes of consumptives. They have been found in churches, in places of amusement. Where will you draw the line as to watching and interfering with the life of the consumptive? Must we not take the broader view, and act on the degree of the communicability, and how far it is practicable to control it, rather than on the mere abstract question whether tuberculosis be contagious or not? The degree, every observer knows, is extremely slight.

The excellent series of observations about the houses is, I believe, subject to several fallacies. In the first place, unless you know the history of the persons themselves, these observations on the houses supposed to be infected are not conclusive. You must know whether or not the individual inherited tuberculosis. I am one of those who believe that the disease is largely hereditary. Of what use is it to say how many living in these houses die of consumption unless you know the history as well as the number of those who have occupied them?

Again, we should bear in mind when discussing the contagiousness of phthisis, how enormously prevalent the disease is, and how difficult it is to draw conclusions when you have the most prevalent chronic disease to deal with. As bearing upon the question of infection from husband to wife, it has been calculated by Longstaff as a mere matter of statistics without reference to the question of contagion, that of every 148,121 men who die of consumption in the ages of married life, there would be 4358 wives who would have consumption—that is, about 1 in 33. Thus, for every thirty-three married men who die of consumption there would be one woman who would have it, as a mere matter of ordinary frequency, whether the disease be contagious or not, and the probability would be a little more for phthisical wives. The number of cases seen in which both husband and wife have been affected is comparatively small. Flint, in over six hundred and seventy cases, noted but five such instances. My record shows more such instances, including one in which a tuberculous husband had three tuberculous wives. Still I have not met with very many, and the chances are always slight that the husband communicates the disease to the wife,

or the wife to the husband. When we take all these facts into account, as well as the strong hereditary tendency of the malady, we must be careful how we draw conclusions in individual instances of apparent contagion.

Mindful of the observations of Dr. Flick, I have for some time questioned myself with reference to houses that I have known for years in which there has been consumption. But I have not taken them in one district, but everywhere. And this seems to me a much fairer way of studying the question, as the indiscriminate selection obviates the likelihood of error from bad hygienic conditions, especially of drainage, that houses near each other might share.

I have many houses in mind in which no case of consumption followed the first. In one the father died of slow consumption twenty years ago. The mother is, as regards tubercle, perfectly healthy to this day. The seven children have grown up into exceptionally healthy young men and women. In another house the wife died of consumption about eighteen years ago. The husband continued to live in the same house, and a family of children have grown up healthy. Another house has been occupied for many years by a consumptive who has had the disease for twenty-five years. Neither his wife nor any of the five children has become affected, though he is in the hands of a physician who does not believe in the contagiousness of the disease, and does not direct the sputum to be disinfected. Another house was occupied for years by a consumptive mother, whose husband had died of the disease many years before in another city. The son and daughter remained in the house mentioned for eight years in perfect health. It has since been occupied by a lady whose history I know, who is also healthy. The son got married about seven years ago, and has lived in various places. Within the last two years he has become a consumptive. His strong hereditary tendency determined the occurrence. I could go on citing instance after instance. I admit they furnish negative evidence. But negative evidence in a matter of this kind is valuable. I am on the whole quite certain that in by far the larger number of cases in which I have known the history of both the house and of the household for a long time, there could not even be any suspicion of house-infection. It is true also that in most of the houses cleanliness and ventilation were well attended to.

Further, in the question of house-infection, we must not overlook the fact that these supposed centers of infection may adjoin, and have common drainage. And, under any circumstances, does it not suggest that possibly there is something wrong in the drainage or subsoil as much as it does infection of the house? The well-known observations of Bowditch and of others have made us familiar with this mode by which consumption spreads in Massachusetts and in the whole of New England.

With reference to hospitals: Consumptive hospitals have been brought forward as a strong evidence of the non-contagiousness of phthisis, though I cannot say that the figures adduced are to me absolutely convincing, and there may be something in the greater prevalence and concentration of the poison that make consumptive hospitals more likely to be sources of infection. I have already referred to the observations and opinions of Dr. Williams and of Dr. Andrew. But as regards general hospitals in which consumptives reside, they certainly cannot be shown to be places of infection. I will quote the remarkable results in the General Hospital of Vienna. That hospital is one of the largest in the world. It is full of consumption, and there were, as we know by some observations made long since, and before the disinfection of the sputum was attended to, in three years 2736 deaths from phthisis, and not a medical officer or a nurse had become infected. I will refer to the record of the Pennsylvania Hospital, which always has consumptives in its wards. I have taken some pains to ascertain the truth in this matter. In my long connection with the institution there never has been a time when there were not cases of tuberculosis in the medical wards, and there have also been cases of surgical tuberculosis in the surgical wards. Of 147 resident physicians that have been in the hospital in the last seventy years, and of whom I have traced the medical history, and many of whom I have personally known and examined, but one has died of tuberculous disease. Two others have at different times shown tuberculous symptoms. One of these is now living in Arizona in fair health. In the other even bacilli have disappeared from the sputa. The one dying did not die for more than five years after leaving the hospital. Moreover, before becoming a resident physician, he was in delicate health, so that it is not fair to attribute his death to his having lived in the hospital.

A stronger statement still can be made with reference to the nurses. Of forty male nurses that have been in the hospital in the last twenty five years, but one has shown any sign of tuberculous disease. He is now a patient in the hospital. He did not become tuberculous until four years after leaving. There have been 163 female nurses whose histories can be fairly well traced. Of 53 that have left the hospital in the last five years we know the present condition accurately. Not a single one of these certainly has had any tuberculous symptoms, notwithstanding that there was always tuberculosis in the wards, always some exposure, and until recent years disinfection of the sputum was not practised, although ventilation was always attended to. There is only one case even doubtful. This nurse has an occasional cough, and is not strong. Her father and mother both died of consumption.

When we take all these facts into account, granting, as I do, that up to a certain extent tuberculosis is contagious, I think that the recommendation of the Council to the Board of Health is the right one. Why fix the brand of leper on a poor unfortunate because he has consumption, when the medical officer can do all that is necessary? He can instruct how to ventilate and keep the house pure, and how to disinfect the sputa. What more could a Board of Health do? What can it do, except in instances of death in which proper disinfection may not be carried out? When death has occurred, and when disinfection is not likely to be practised, it would be proper for the Board of Health to interfere. Under other circumstances, why should we place a stigma on the consumptive, why have him pursued from house to house, why have him a marked man, why have the house a marked one? Why give it a bad

name and injure the landlord because there has been a death from consumption in it? I think that the resolutions offered by the Council cover the whole case. No human being will suffer. It will only enforce on medical men the necessity to insist on proper disinfection and proper hygiene. It will do as much as possibly can be done, and as much as any Board of Health can do.

With reference to hospitals for the consumptive, there is a great deal to be said on both sides of the question. Undoubtedly larger means of separating the sick from the well are desirable. But whether this can be made in any way obligatory is doubtful; large social questions and questions of finance arise which take the matter far beyond our power materially to influence.

We must not overlook the strong hereditary tendency to the disease. If you want ever to get rid of consumption, it is not going to be simply by the disinfection of sputa and similar means. It will be largely by the prevention of the marriage of tuberculous patients. There you strike at the root of the evil. Until hygiene, preventive medicine, and law have reached that point, I think that we must let this question take care of itself, doing the best we can to limit the ravages of the disease. I admit that it would be most desirable if we could separate the consumptive from the well. If the State were rich enough to form colonies in climates in which consumption will not flourish, that would be a most admirable means.

Let me say that it is not because I do not believe that phthisis is communicable that I oppose the contemplated action of the Board of Health to declare the disease contagious, and to register consumptives, but because I believe that the means proposed will produce hardship without corresponding value, and that they are both unnecessary and insufficient. The Board of Health has already the right, and may well enforce it, to have any house that, whatever the cause, has a bad sanitary record, put in better order. Moreover, it can do much in destroying other sources of infection, such as diseased meat, the milk of tuberculous cows, in improving drainage, in favoring open spaces that air and sunlight may get into houses. But let it leave the care of the individual where it belongs—to the conscientious physician.

DR. JOHN B. ROBERTS: It seems to me that this question is almost exactly the same as the one with which surgeons struggled ten years ago. I was one of the conservative ones who did not at first practise antisepsis, but employed half-way measures, and saw all my cases suppurate. This is the point to which the question of tuberculosis has come.

I think that Dr. Da Costa's statement that there are a large number of cases all over the country, which he uses as evidence that the disease is not certainly infectious, is really an argument on the other side. It is so because there is infection. There are so many hereditary cases because infection of the parents has so weakened the tissues that a lowered resistance is transmitted to the children, and they cannot repel the invasion of the bacilli.

It is said that the doctor can do all that is necessary, but Dr. Da Costa has said that he has known of cases where the physician would not take any precautions. That is a reason that the Board of Health should step in among the poor and see that the houses are clean. We see this in diphtheria. It is not a question of damage to landlords. It would be an advantage if everyone knew that every house was disinfected, either by the willing efforts of the people, or owners, or by the Board of Health. There seems to be no reason why there should not be a report to the Board of Health if it will act in a reasonable manner. There is no expectation that the Board of Health would take the same measures as in typhus or typhoid fever. It is only a few years since typhoid fever was placed on the contagious list. If the matter had been discussed publicly there would no doubt have been many men on both sides—some for, some against putting typhoid fever on the infectious list.

It might be well to mention what has been done in other places. In February, 1892, at a conference of the medical staff of the Manchester (England) Hospital with the medical officers of health and others, it was unanimously resolved that it was desirable that certain cases of phthisis should be notified to the medical officer.

Dr. Hermann G. Biggs, the Chief Inspector of Pathology, Bacteriology, and Disinfection in the Health Department of the City of New York, has sent to the Health Board a long statement regarding the contagiousness of tuberculosis, accompanied by a number of recommendations. He says:

"First. Tuberculosis is a contagious disease and is distinctly preventable.

"Second. It is acquired by the direct transmission of the tubercle-bacilli from the sick to the well, usually by means of the dried and pulverized sputum floating as dust in the air.

"Third. It can be largely prevented by simple and easily applied measures of cleanliness and disinfection."

His recommendations include:

"That there be systematically disseminated among the people by means of circulars, publications, etc., the knowledge that every tubercular person may be a source of actual danger to his associates, and his own chances of recovery diminished, if the discharges from the lungs are not immediately destroyed or rendered harmless.

"That all public institutions, such as asylums, homes, hospitals, dispensaries, etc., be required to transmit to the Board of Health the names and addresses of all persons suffering from pulmonary tuberculosis.

"That all physicians practising their profession in the city be requested to notify this Board of all cases of pulmonary tuberculosis coming under their professional care."

The North London Hospital for Consumption issues directions to its out-patients and to its ward-patients, recognizing the contagious nature of tuberculous phthisis and suggesting precautions.

The Royal National Hospital for Consumption, Ventnor, has this to say:

"Patients are earnestly requested not to spit on the ground, floor, or fire-place, but to expectorate into the proper vessel. When this is not possible, the handkerchief should be used without fail; but in order that the expectoration may not become dry it has been arranged that a clean pocket-handkerchief shall be supplied to each patient daily, the soiled one being at the same time removed for the double purpose of disinfection and

washing. *It is to be distinctly understood that spittoons shall always be used when possible, and that the handkerchief is only supplementary, to prevent spitting upon the ground.*"

The Manchester Hospital for Consumption takes a similar position:

"All matter coughed up from the chest should either be spat in the fire or should be received into a vessel lined in such a way with a piece of paper that the paper and its contents may be lifted out and burnt.

"Rags that can be burnt should be used instead of pocket-handkerchiefs, and if a pocket-handkerchief be used it should be well boiled before the matter upon it has had time to become dry and powdery.

"N. B.—The Medical Officer of Health for Manchester undertakes to purify, *free of cost*, any house that may be notified to him by competent medical men."

Last year the Northwestern Branch of the Society of Medical Officers of Health drew up a memorandum on the subject, which has been pretty widely distributed in the North of England. In this memorandum the infectious nature of consumption is definitely laid down, and dried sputum in the form of dust is indicated as the vehicle of contagion.

The County Borough of Oldham, in England, gives similar "precautions against taking consumption."

The French Ligue Préventive contre la Phthisie Pulmonaire says:

"The most frequent and powerful source of infection lies in the expectoration of consumptive patients. Although almost harmless so long as they remain in the liquid state, the sputa become especially dangerous when they are reduced to dust. They quickly take on this form when they are projected on to the ground, the floor, the walls; when they soil clothing, counterpanes, bedclothing, curtains, etc.; when they are received into handkerchiefs, napkins, etc."

With this evidence of scientific work in other places, can the College of Physicians of Philadelphia deny the contagiousness of phthisis, or doubt the advisability of the Board of Health knowing and registering the houses of at least the poor and careless, in which the germs of tuberculous consumption are threatening the public safety?

While there may be a few who believe in the non-contagiousness of consumption, the vast majority does believe that it is contagious to a certain extent. It is the same old story of antisepsis and sepsis. The College of Physicians should go on record that consumption is contagious more strongly than appears in the report of Council. In the second place, something should be done. That seems to me to be in the direction of letting some official know that the consumption-bacilli are to be found in a certain locality. Not the physician, but some central body should have the authority to know and the authority to enforce such measures as will limit the spread of the disease among the poor. If we limit it among the poor we limit it among the rich.

Dr. William Osler (Baltimore): The question may be thus briefly stated:

First. Following a primary law of parasitism, the bacillus tuberculosis frequents chiefly that organ in its host which communicates most freely with the exterior. Just as countless thousands of ova are thrown off from the intestine of the bearer of a tapeworm, so from tuberculous lungs in a state of softening and cavity-formation, countless millions of bacilli are cast out daily with the sputa.

Second. The widespread diffusion of the parasite outside of the body has been demonstrated in the infectiveness of the dust and of the scrapings of the walls of rooms and wards occupied by patients with pulmonary consumption. Moreover, the greater prevalence of tuberculosis in crowded communities, the enormous mortality from the disease in prisons and institutions, and its frequent occurrence as a house-malady, suggest that the conditions favoring its continuance are those which foster the growth and spread of a specific contagion.

Third. In the language of parasitology the lungs constitute the chief seat of election! But, apart also from gross pulmonary lesions, the proportion of autopsies in which the bronchial glands are found tuberculous speaks unmistakably for direct infection in the exercise of their function as dust-filters.

On these grounds I believe that the registration of pulmonary tuberculosis would be beneficial—enforcing attention to those sanitary details so apt to be slighted or overlooked, and diminishing directly the danger of contagion in the community.

Infection through food is closely related also to the endemic prevalence of tuberculosis. The incidence of the disease in the mesenteric glands of infants indicates that the gastro-intestinal canal is a portal of infection only a little less wide than that of the respiratory system.

The question of tuberculosis is not, however, settled with the disinfection of the sputa of consumptive patients.

The hereditary transmission of the disease must be accepted, though an estimate of the frequency of this mode of infection must necessarily be uncertain, but for certain forms Baumgarten's theory of latency is particularly suggestive. Tuberculosis has been well called the *pébrine* of the human race. The analogy is striking, for not only, as you will remember, is the parasite of the silkworm-disease transmitted by direct contagion, but it also infests the eggs, which hatch, and may pass through various stages of development before they are finally destroyed.

Lastly, and here is consolation, the conditions which render individuals more or less immune scarcely yield in importance to those which maintain the vitality of the tubercle-bacilli in a community. So widespread is the seed that few of us escape infection, and the statistics of the Paris Morgue show that in more than 50 per cent. of adults the germs not only gain an entrance, but actually effect a lodgment. As a factor in tuberculosis, the *soil*, then, has a value equal almost to that which relates to the *seed*, and in taking measures to limit the diffusion of the parasite let us not forget the importance to the possible host of combating inherited weakness, of removing acquired debility, and of maintaining the nutrition at a standard of aggressive activity.

Dr. H. C. Wood: I came here not to speak but to learn, and thus far have been quite successful. I wish to quote from a letter from Dr. Billings which has been placed in my hands. He says: "I should like very

much to hear the discussion, but probably should have little to say, since I am doubtful as to what the decision of the College should be on this point. I presume that there are about six thousand people in Philadelphia affected with consumption, and that a considerable proportion of these have contracted the disease in infected houses. If it were possible by a systematic notification for the Board of Health to locate a considerable number of these infected houses, what steps would it take to purify them? How would it deal with those of the poorer classes who are affected with this disease, and with their furniture, bedding, and rooms? Until these questions are answered, I do not find it possible to form a definite opinion as to whether it is worth while to put in force a compulsory system of notification. Some of the worst infected rooms are probably those occupied by the criminal class, which is especially liable to this disease. For example, the Eastern Penitentiary is certainly thus infected; but in this I presume the Board has no jurisdiction.

"It occurs to me, that if the system of notification is to be tried, it might be best to commence with a limited area of the city in which the death-rate is now high; for example, the Seventeenth or the Seventh Ward, and see what results in diminishing the proportion of cases in this area can be obtained in the course of two or three years."

This thought has occurred to me, that has not been touched upon by any of the speakers: In a case of diphtheria the Board of Health is notified; the patient dies or gets well, and the room is disinfected. Suppose, however, a case of consumption: The Board of Health is notified, the house is disinfected to-day, but reinfection occurs to-morrow, and the end need not come for four or five years. Unless you add the power to forcibly remove the patient and shut him up in a hospital-jail where you can confine and permanently disinfect him, I do not see how you are going to get any good results from the process of disinfection. As far as disinfection goes, unless you can prevent to-morrow's reinfection, I see little use in to-day's disinfection. If, however, the Board of Health could disinfect houses in which phthisic cases have died, something might be achieved, but the ordinary death-notice is all the notification required for this.

Dr. Thomas J. Mays: It has been stated that consumption is less frequent in those parts of the Fifth Ward in the neighborhood of Spruce and Pine streets, and becomes more prevalent as we approach the poorer portion of the city. Dr. Flick's investigations extended over only a limited period of time, say twenty-five years. In that time he finds that about 25 per cent. of the houses in the Fifth Ward have become infected. I hold that if the investigations had extended over a longer period—say fifty, seventy-five, one hundred, or one hundred and twenty-five years—he would have been able to show that nearly every house in that ward was infected, according to the contagion-theory, that in nearly every house in that ward a consumptive had lived and died. The same argument applies to the investigations made in New Haven. I have in my possession a book reporting similar investigations made by Dr. Riffel in two old towns along the Rhine in Germany. He investigated the death-rate from phthisis in these towns for fifty, seventy-five, one hundred, and in some cases one hundred and fifty years. He found in one town at least—Karlsdorf—that at some time or other nearly every house had had a case of phthisis in it.

Dr. Flick also refers to the diminution of the phthisis-mortality in Berlin, London, and Philadelphia. I think that if he had consulted the death-rate from phthisis in these cities he would have found a gradual diminution in the death-rate from consumption before the bacillus-era began in 1882. I went over this subject some years ago and I found that in every large city there was a gradual diminution in the death-rate. Dr. Flick claims that the diminution in the death-rate of consumption, since 1882, in this city, has been due to the disinfection of the sputum. His own figures show, however, that there occurred a larger number of deaths from this disease during the nine years following 1882 than during the nine preceding years. In what way this makes a favorable showing for the theory of disinfection I am at a loss to understand. So far as I know there has been no Board of Health regulation in this city. So far as I know there has been no Board of Health regulation in Berlin, or London, or any other city, yet their deaths are gradually diminishing in number. If the gentlemen on the other side will look backward a hundred years they will find that the very experiment which they are so anxious to try now was tested with the utmost rigor, from 1782 to about 1855, in Naples. It was decreed that every physician who neglected to report a case be fined one hundred and eighty dollars; that the ceilings, walls, floors, doors, and windows of the room in which consumptives died be torn out and burned; that the bedding and furniture be also burned, and that such dwellings were not to be occupied for a year. The result was that the family with phthisis was shunned and driven to want. Houses in which consumptives died depreciated in value. The sick were neglected and inhumanly left to die, away from their families and friends. Did any good result from these laws? Brehmer states: "Concerning a diminution in the rate from phthisis in Naples the medical historians of that period are ignorant." According to Uffelmann (*Berlin. klin. Wochenschrift*, 1883, p. 369), Dr. de Renzi, the medical historian of Italy, states that the injury which had been inflicted on Naples by these laws was simply indescribable and he denounces the Neapolitan faculty in the severest terms for participating in their introduction.

In vol. xlv, p. 112, of the *British and Foreign Medico-Chirurgical Review* it is stated that Drs. Spatuzzi and Somma, "who have paid great attention to the mortuary returns in that city (Naples, about 1860), affirm that one-sixth or a seventh of the whole mortality is due to phthisis," and that Dr. de Renzi "marvels greatly (in 1863) that the city of Naples is fully as much liable to phthisis as either London or Paris, though the salutary condition of the climate should render it far less common."

If the death-rate from consumption was the same in Naples at the time segregation ceased as it was in other cities in which segregation was not practised, it is self-evident that such a measure can have no influence in diminishing the death-rate from this disease.

Dr. James Tyson: I had intended to say something this evening on this important subject, but almost every

point which occurred to me has been so well treated by others that I hesitate to add anything. I admit all that has been said with regard to the contagiousness of phthisis, as determined by experiment, but as to the actual spread of consumption from one person to another as the result of association—as to the degree of contagiousness, in a word—I agree entirely with Dr. Da Costa. Admitting the correctness of Dr. Flick's studies and Cornet's observations, it still comes to this, that the physician is competent to take care of this question without the intervention of the Board of Health. Just as the surgeon is qualified to take care of the matter of antisepsis and asepsis in his management of surgical cases, so the physician is competent to take care of the disinfection of utensils used by consumptives and the destruction of the germs which may be the cause of the disease, the more especially as such disinfection is acknowledged to be of the easiest kind. What Dr. Roberts has just said with regard to the situation ten years ago as to sepsis and antisepsis, could as well be alleged in favor of the position that I take—that the physician is competent to handle the difficulties. The surgeon did not call in the Board of Health to help him under like circumstances, but fought the battle alone, and won it triumphantly. The question has been studied experimentally and clinically, and we know exactly where to put our fingers to check the spread of consumption, as far as this is possible. We must attack the disease in two ways: first, the contagion must be destroyed as far as possible with the means at our disposal, and second, we must seek to change the soil on which it is known that the bacillus flourishes, by improving the general health of the individual, and thus increase his ability to repel the invader. I feel that we are entirely competent to handle this question without the aid of the Board of Health.

DR. ABBOTT: I have listened with much interest to both sides of the discussion, but must confess that I am not yet quite secure in my mind as to the proper course to be pursued. I am strongly inclined to the views expressed by Dr. Billings in his letter to the President. Tuberculosis is a widespread disease, with manifold expressions, and if our efforts are to be directed against it, in the full sense of the term, the problem is certainly beset with many difficulties.

In connection with the subject under discussion, the question that has constantly presented itself to me is: If the College sees proper to recommend that all houses in which the disease is located be reported to the authorities, has it any guarantee that their conditions will be improved? The object in reporting these houses is to secure complete disinfection of them, a process requiring conscientious attention to most minute details, to say nothing of a full knowledge of the requirements of the cases. If the Board of Health is in a position to assure us that these demands can and will be met, then I am in favor of the resolution. If not, then we have had a long discussion with but little result.

The ultimate object arrived at in the resolution I consider as most desirable, but will it be attained if the resolution is passed? We have abundant evidence in justification of the belief that localities occupied by persons suffering from the pulmonary form of tuberculosis, particularly, may and do become centers of infection, and it is highly desirable that such places should receive the attention that their character demands. Much has been said here this evening concerning the prevention of the spread of this disease by disinfecting the sputum, and this point has been accentuated as if the danger ended here. The danger does not end here. Sputum collected in a receptacle may remain perfectly harmless without disinfection or any other treatment whatever. The danger lies in the sputum *not* collected, but spat upon the floor, dried, ground into dust by the feet of passers-by, and ultimately inhaled into the lungs—a condition of affairs often seen in dwellings of the poor. The predominance of pulmonary tuberculosis over other manifestations of the disease is certainly, in part, accounted for in this way. Dr. Da Costa in his remarks has said that "bacilli" are everywhere present, and if this is the case how are we to escape them, etc.? His use of the term bacilli in its generic sense is misleading; I can hardly think he meant that *tubercle*-bacilli were everywhere present, for this is not the case. They *may be* present wherever tuberculous individuals *are* present or have been present, but to say that they *are* present in all places does not accord with the results of observation.

DR. FRANK WOODBURY: The facts collected with so much commendable diligence by Dr. Flick are susceptible of quite another interpretation. They certainly do not prove consumption a contagious disease, or that the bacillus tuberculosis is its sole cause. If he had confined himself to the task of showing that want of sunlight, dampness, and other mal-hygienic conditions were efficient causes of phthisis his data would have been equally applicable. Or if he had intended to prove that the habitations of some of the poorer inhabitants of this city were likely to act injuriously upon the occupants, so as to predispose them to phthisis, we might have been willing to go with him almost to any extent in making application to the Board of Health to destroy these sources of disease. We might admit that by adopting such drastic measures the mortality from tuberculosis would undoubtedly be greatly reduced. The total extinction of pulmonary consumption, under present conditions of civilized life, however, is entirely impracticable.

It may be admitted, if the proposed plan of registration and inspection were rigorously carried out, that the results would apparently support the claims advanced. The number of cases reported would certainly diminish to a remarkable degree; but the real explanation, however, of the diminution would be that a large number of cases would be concealed, and deaths would be reported as from other causes. Moreover, a large number of cases would object to the solicitude of the Board of Health for their welfare and leave the city. Physicians would have their sympathies appealed to by relatives, who might wish to conceal from the patient the fatal character of the malady, and would be in a dilemma between duty to their patients and duty to the State. In fact, registration would eventually divide physicians into classes—those who reported their consumptive patients and those who did not. The physicians having the reputation of not reporting their cases would naturally have a larger *clientèle* than others.

DR. S. SOLIS-COHEN: The question to be considered is simply this: Granting all that may be said concerning

the etiologic relations of the bacillus of Koch to tuberculosis, and granting all that is said as to the spread of infection from persons affected with tuberculous disease—on the whole, will the health and comfort of the community, including both the well and the sick, be better promoted by having all cases of tuberculosis registered or by not having them registered? So far as the sick are concerned, the disadvantages of registration are obvious. So far as the well are concerned, Dr. Da Costa has shown that the reasons advanced in support of the proposition that it is necessary to have cases of tuberculosis registered in order to protect the health of the community, cannot withstand critical analysis. I believe, moreover, that registration would be a detriment to the community, for the reason that when of two measures to prevent an evil, attention is concentrated on the less efficacious, the more efficacious is likely to be neglected. If we direct our attention too strongly toward germicidal measures we shall lose sight of the more important measures that relate to the general sanitation of cities, of houses, and of individuals. Tuberculosis among men is to be prevented by increasing the vitality of the race, by preventing the marriage of tuberculous and otherwise unfit persons, and by perfecting the sanitary environment and life of the individual. The true prophylaxis against tuberculosis begins, therefore, before conception; but as society has not reached the stage of development where such prophylaxis can be generally instituted, it becomes all the more necessary to insist upon those practical measures of individual and civic hygiene which must be our greatest dependence and to oppose whatever shall tend to obscure their importance.

As has been said by Dr. Woodbury, if Dr. Flick had started out to prove that consumption flourishes in overcrowded places and where misery, poverty, filth, and vice are congregated, his statistics could not be more admirably adapted to enforce that conclusion; but to prove that tuberculosis is contracted only or chiefly by living in houses in which persons having tuberculosis have previously resided, would require that a census be taken to find out concerning every house in the city whether at any time there had been a patient with tuberculosis living or dying in the house, and if so, how many cases had followed and at what intervals, and also to determine how many cases of tuberculosis had developed among those living in houses in which no one having tuberculosis had previously resided. Until statistics of this character are at hand, the case against the so-called infected houses, in districts in which the city, the houses, and the lives of the people furnish so many potent causes of impaired vitality, is at least "not proven." But grant that the proof of infection in houses is conclusive. Suppose that the houses are thoroughly disinfected, and even, referring to Dr. Wood's point, guarded against reinfection—what have we gained? We are told by the highest authorities that the bacillus of tubercle is about us everywhere. It exists, save at certain altitudes, or upon the sea, or in other specially favored regions, in the air we daily, momently breathe. Everyone is at some time exposed to the danger of inhaling it, and that it is inhaled by everybody is shown by the results of autopsies upon persons having no tuberculosis elsewhere, but in whom the bronchial glands are infected with the tubercle-bacillus. I believe that, according to some statistics, the proportion of persons so infected has been placed at 50 per cent. Is it not clear that, as was said by the President of the College in his Annual Address, in order to make the Board of Health laws effective, there would have to be instituted a system of espionage so that the tuberculous patient could be followed every day from the time of his rising up to that of his lying down, while seated in his house, or while walking by the way, to make sure that by no possibility should his sputum be deposited in any place where it could become dry and be carried into the air—a thing which is manifestly impossible. But if instruction only is to be given and no such rigorous supervision of individuals attempted, it is within the province and within the power of the attending physician to instruct his patients, and the intervention of the municipal officer is not required.

Therefore, because of the impracticability of this registration to effect anything positively, and because, negatively, it will have the effect of diverting attention from the fact that these streets or alleys, to which Dr. Flick directs attention, should be cleansed and widened, the houses properly drained and ventilated, the people properly fed and clothed, and otherwise protected from exhausting and depressing influences, I consider it to be the duty of the College to place its strong word on record against the proposed legislation.

Were the proposition in favor of a municipal hospital for tuberculosis, separated from the other recommendation, and properly safeguarded, I should be glad to vote for it.

Dr. Richard A. Cleeman: One very important point has not been alluded to. Statistics show that the death-rate from consumption is almost the same in every community, year after year. If there is any diminution, it is very small. This is directly opposed to the idea of the contagiousness of the disease. All other contagious diseases vary very much in their death-rate at different times. There is only one explanation by which we can conceive that phthisis is contagious and the death-rate always the same, and that is, that the whole of the community is thoroughly infected with the tubercle-bacillus, and that in the community there is a fixed number who are susceptible to the disease. Just as, statistically, we can calculate how many giants or how many dwarfs are in a community, so can we estimate the number of persons susceptible to phthisis.

In this view of the case, with the bacillus tuberculosis spread over the whole city, measures to be effective must be of a very extensive character. The mere reporting of a case now and then—for I believe the rule would be often neglected—would have very little effect. Measures to be effective must be thorough and they are the methods of general hygiene.

Dr. James B. Walker: We must look at the practical side of this matter, and ask what will be the benefit from registration? How much has typhoid fever in this city been diminished by the fact that we report our cases? Not in the least. The disinfection of the stools which the physician has directed has lessened the number of cases, as similar attention to the sputum may in phthisis. I am against placing phthisis on the list of diseases to be reported, for many reasons. I do not believe that this would confer a single benefit upon the city or its inhabitants. The physician is capable of doing all that

the Board of Health can, without the manifold evils and annoyances of public registration. The College should go on record against the registration of the disease. It should go on record also as believing that the disease is possibly contagious, and should recommend physicians to use the most strenuous efforts to prevent the transmission of the contagion.

DR. DA COSTA: I used the expression that the tubercle-bacilli were everywhere. A bacillus that is on the pavements, and in houses, that is wafted about in the air, that exists in milk, and on fruit sold in the markets, and, as has recently been demonstrated, is on the very money that we handle, may well be described as a bacillus that is everywhere. The tubercle-bacillus is so diffused that it can, indeed, be considered as everywhere present, and it is scarcely a figure of speech to so describe it.

With every word that Dr. Roberts has said, I agree. There is not a direction he has read I would not subscribe to and endeavor to enforce as an officer of an institution, or in private life. I hope, indeed, that every Fellow will go away to-night imbued with the necessity of carrying out all measures that have been brought forward with the view of destroying this scourge. But is it not better that we should do this as individual health-officers, than to have it done in a necessarily perfunctory manner by a Board of Health? The only way that the Board of Health could radically act to destroy the tuberculous material would be to burn every house that was supposed to be really infected, separate the tuberculous husband from the wife, take every child away, and cause such an upheaval in society as no community would submit to.

DR. FLICK: Dr. Williams, of the Brompton Hospital, has been quoted as an opponent of the theory of contagion, but he has written a paper in which he shows that a large number of nurses of the Brompton Hospital have contracted tuberculosis. I think that he has traced some fifteen or twenty cases.[1]

As to the ubiquity of the tubercle-bacillus, Koch and Cornet have disproved it. They have shown that the contagious environment of tuberculosis is limited. Cornet has made experiments with dust taken from the streets and many other places at random, and was unable to produce infection by inoculation. He has, moreover, made an investigation of the health of the street-cleaners of Berlin, and has found them freer from tuberculosis than any other class. It must be borne in mind that the isolated cases of infection of fruit and other articles which have been referred to are traceable to handling by consumptives. Many of the fruit-stand dealers have consumption.

With regard to the endeavor to ascribe the occurrence of the disease in certain houses to dampness, that can be disposed of in a moment. In one of the worst infected streets in the Fifth Ward, say Bay Street, at least 20 per cent. of the houses have not had a death from tuberculosis, although the sanitary condition is as bad as in the infected houses. Dampness can have no influence here.

As regards infection in hospitals, as I have said, Williams has written a paper in which he shows that fifteen or twenty nurses have contracted the disease in the Brompton Hospital. Cornet has written an elaborate history of hospital-infection. He has taken the general hospitals of Germany in which the nurses are permanent, and he finds that as high as 62 per cent. had tuberculosis. In my own class of residents at Blockley, sixteen in number, two died within three years of the disease, and I myself was for a time believed to be a victim.

It has been argued that we ought to trace the history of these houses for a longer period, say one hundred years. There is a limit to the infecting power of tubercle-contagion. What that limit is I cannot say; probably not very long. Unless cases occur within a few years of each other to keep up the chain of infection, the houses are no longer infected houses.

Italy has been quoted as an evidence of the non-effectiveness of preventive measures. I am surprised that this quotation is made so frequently after what has been written. I have shown by careful quotations from contemporary authorities—and authorities that cannot be doubted—that at the time when the laws were instituted in 1782 the mortality was about 10 per 1000, and that when preventive measures were abandoned, the mortality was so low in the extreme southern part of Italy that it was practically *nil*, 0.19 per 1000. Many who have written upon the subject have overlooked the fact that it is not the city of Naples but the kingdom of Naples that is spoken of. This comprised the southern half of Italy and Sicily. At first the northern part of Italy opposed the view of contagion and refused to accept any preventive measures. After some years it adopted preventive measures, but even at this day the mortality in the northern part of Italy is twice what it is in the southern part. These preventive efforts proved another point, and that is the local infection. The only practices that were of any benefit in the Kingdom of Naples were, first, isolation; and, second, compulsory disinfection. The preventive measures circled entirely about the household. The Italians did not know where the infection came from, but adopted crude measures of prevention. Yet with their crude measures they reduced the mortality to a minimum, and except for the fact that Italy became a health-resort for tuberculous persons, it probably now would have no tuberculosis. The statistics show that those parts of Italy that are health-resorts for tuberculous patients run up the mortality. This has been as high as 4 per 1000 in some of the resorts, but in the rest of the Kingdom of Naples the mortality is a fraction above 1 per 1000.

As to the competency of the physician to meet this question. In connection with this subject, we must bear in mind that every infectious disease is a law to itself. It is not fair to apply to tuberculosis the laws which govern diphtheria, smallpox, etc. The infecting material in tuberculosis is easily controlled. It comes from a single source. In smallpox it is difficult to control. If it were possible to sterilize all the sputa of consumptives we would not need disinfection. Such a thing is impossible, however, and therefore it is necessary that the room be disinfected. This requires great care, and unless the family is willing to undergo the expense it cannot be accomplished. If the physician were to devote half of his time to bring about proper disinfection he could not do it effectively.

Dr. Cleeman has advanced an argument against con-

[1] British Medical Journal, September 30, 1882.

tagion, which, strange to say, has been made for the other side by Dr. De Forest. Dr. De Forest claims that inasmuch as the number of infected houses is limited, the mortality rate should remain the same every year, because the number of exposures remains the same. The centers of infection remaining the same, the deaths should remain the same.

Tuberculosis and typhoid fever have been compared. The reporting of typhoid fever cannot bring about any results unless the lessons taught are acted upon. If the water-supply were made better we should have no typhoid fever. There is no analogy between typhoid fever and tuberculosis. Tuberculosis is infectious from the point at which it exists; typhoid fever infects our drinking-water. There is little danger from the room occupied by the typhoid-fever patient. The cases are not at all analogous.

A vote was then taken on the amendment offered by Dr. Flick; it was lost, and the original resolutions, as proposed by the Council, adopted, the President being requested to appoint a committee of five to present them to the Board of Health.

CORRESPONDENCE.

THE CLIMATOLOGY OF NEW MEXICO AND ARIZONA.

To the Editor of The Medical News,

Sir: In an article entitled "Health Resorts of the West and Southwest," by Dr. H. G. Wetherill, appearing in The Medical News, December 16, 1893, certain statements have been made regarding New Mexico and Arizona that certainly need correction. From the character of the article, they are either mistakes of ignorance or from information derived second-hand.

After speaking enthusiastically of Colorado and Southern California, the writer goes on to say that New Mexico, Western Texas, and Arizona are different in topography and climate from Colorado. To anyone familiar with the Territories in question, this criticism is faulty. Those who by residence or travel are fitted to judge know that the difference is simply one of degree, the general climate both of these Territories and of Colorado being that of an elevated, dry plateau, with a varying amount of moisture.

But the main errors and statements which this letter is intended to correct are not those of simple topographic conditions. The author says:

"In Southern New Mexico, Western Texas, and in Arizona, the elevation is less, the soil is different, the water so alkaline as to be distasteful and disturbing to those not accustomed to it, the rainfall much less, and the dust dreadful. In addition to all these, the hotels in Albuquerque, El Paso, and Phœnix are bad beyond endurance, the food is wretched, and the people, with a few exceptions, are not attractive companions. A Territory that has no more in associations or natural advantages than this, and is by reason of its heat, dust, bad water, and poor domiciles so uncomfortable, and is in addition as unhygienic as the filthy huts of the Mexican and Indian population can make it, is no place for a delicate Eastern invalid with a cultivated taste for many things that have become necessaries of life and are here unattainable."

I have reproduced this paragraph in its entirety, because there are sufficient witnesses to the falsity of those remarks, either in the shape of residents of this Territory, or visitors who, after spending a greater or less time, have returned to their Eastern homes.

To take up his criticisms *seriatim*: The Doctor doubtless knows that the main element in the climatic treatment of tuberculosis is the dryness and equability of a climate. He should also be aware, if he would take the trouble to study the Signal Service Reports that can be had on application, that New Mexico and Southern Arizona are the driest parts of the United States. He should also be aware that with a minimum amount of rainfall, there is also a greater amount of dust, which is probably experienced during the dry parts of the year in his favorite Eastern home. But this dust is not irritating; it is not permanently present, and it is not of daily occurrence; it is perceptible simply by contrast with a damp, moist country; the presence of dust is a necessary accompaniment of the absence of humidity. The heat he complains of is not excessive; it is not, so to speak, perspiratory heat; it is not a heat that compares with that of a short Eastern summer; it is not a heat that depresses the system, and renders heat-strokes common; it is not a heat that is followed by the electric disturbances that he experiences in his Jersey home. It is a heat that is felt simply on account of the rarefaction of the atmosphere; it is a heat that is perceptible in the sunlight, and, from the very rarefaction of the atmosphere, the shade is a cooling, grateful comparison. This heat that he seems to find so fearful has never been complained of by the residents of the Territories, and not even by those who have been sent here in a debilitated condition in search of health. It is a stimulating, refreshing, vivifying heat, not a depressing, stupefying, exhausting heat.

The bad water that he also lays unusual stress upon, I fear must exist simply in his imagination. It may be that he did experience one or two cases of alkaline water, but alkaline water in itself is not injurious. As a diuretic, as a flusher of the kidneys, as an excretory, generally carrying off rapidly and freely the waste-products of a disturbed system, it has no equal, and from some inherent quality, like that of the Delaware River, it possesses the peculiar faculty of purifying itself.

The poor houses and unhygienic conditions to which he alludes exist only in the houses of the extremely poor, and even they are more sanitary and are better fitted to their requirements than the houses and tenements of his own pauper population; but as a Westerner if visiting the East would not, in common justice, consider that the slums were an evidence of Eastern civilization, so he had no right, except the right of a disordered digestion, to consider the adobe houses of our Indian half-breeds an evidence of Western civilization.

The remark regarding the hotels along the line is, to say the least, unfair. The hotels in this locality will compare favorably with any hotel in any Eastern section he may pick out, and in any city of three times the size of those he alludes to. Luxuries, which he seems to consider as unattainable here are within the grasp of the poorest. California fruits, vegetables, our own grapes, are at our doors at a lower price than he pays

for them. The opinion of unbiased, unprejudiced observers has been that in the towns which he so remorselessly criticises the luxuries of life are attainable at less, or at all events at no greater price than they cost in the East. I doubt if there is anything which the most pampered, homesick, lungsick, querulous, cranky invalid could demand that cannot be obtained if he desires it, and at a trifling additional cost, should it not be already put within his reach.

But the meanest, the most unkind, the most uncalled-for criticism is upon those who have taken up their abode for better or worse within the borders of these Territories. He states that the people are not attractive companions. As a resident physician for five years within the city of Philadelphia and its vicinity, I can simply say that this statement is absolutely false. The people who have come here, either for health or in search of adventure, mercantile or otherwise, have been those who, accustomed to the best society of their native places, demand and will have all that makes congeniality, friendly association, and a kind regard for each other. In no place in the United States can there be found as cultured, refined, courteous men and women in proportion to the population as upon this former frontier line. The cricicism is at variance not only with the experience of those who have lived here for a number of years, but will not be borne out by the opinion of visitors in search of either health or pleasure. It is a misleading, unfounded criticism, which needs to be supported by better evidence than mere statement. I would like to know upon what personal experience the gentleman founds his remarks, as travel upon the railroad through the Territory of New Mexico is mostly done at night, and I am certain that so far as Albuquerque is concerned, he never pretended or never attempted to make himself acquainted, nor to seek to know any of the people of this town.

Another remark, as to the fact that in Arizona pulmonary tuberculosis is common and fatal among the native population, is not borne out by facts. He has mistaken tuberculosis for syphilis. This fact I have proved to my own satisfaction by a four years' experience as physician in charge of an Indian school, as well as by twelve years' acquaintance with this country, and an intimate, personal familiarity with the physicians practising therein.

I regret that it has become necessary to contradict so many of his statements, but such misleading opinions, based on but slight and in many cases no acquaintance with this country are so current among physicians of the extreme East that the time has come to put ourselves right before the profession. The leading physicians and specialists of the great Middle States, with Chicago as a center, have realized and known for the last fifteen years the capabilities of this Territory. They have made climatology a study and they are aware that within the banks of the Rio Grande Valley, from El Paso on the south to Embudo on the north, there extends a strip of country with a minimum rainfall and with a moderate degree of heat; from past experiences, they are learning how to utilize it. These same physicians are becoming acquainted with the fact that they cannot either conscientiously treat patients or give them advice regarding their every-day life from their offices in Chicago, but advise them to seek this country, and reside in that part of it to which a resident physician shall assign them.

It is well-nigh time that our extreme Eastern *confrères* gave up this habit of sending all classes of tuberculous trouble to an elevated region without regard to their condition; it is well-nigh time, too, that they stopped giving their patients elaborate instructions how and what to do on their arrival and residence here, unless those same Eastern physicians will take the trouble, will be conscientious enough, to visit, make a study of this plateau, exchange opinions and results, and then draw their own conclusions. It has not been three weeks since we were forced to correct an opinion by one of the brightest medical minds of this country, that a certain disease was frequent in New Mexico and Arizona, when a correspondence among resident practitioners disclosed the fact that no case had ever been known, extending over a period of practice amounting to twenty-five years.

It is time that this matter should be freely, frankly, and fairly discussed. I admit, and knowingly admit that there is no place upon this plateau to which all and every kind of tuberculosis can be sent. For the past twelve years, I with other physicians have been doing a sifting process among invalids sent to this country, advising one to stay here, the next to go higher, the third to go lower, and I regret to say, the fourth to go home.

All that we ask either as physicians or residents of this Territory, in common justice to ourselves and our profession, is a knowledge of our capabilities, of our resources, and equally so, a knowledge of those things in which we fall short; and we demand as a right, that this knowledge shall be obtained from reliable sources and after due, diligent, and painstaking inquiry.

James H. Wroth,
Ex-President of the New Mexico Medical Society.
Albuquerque, N. M.

NEWS ITEMS.

Dr. Walter D. Green has been appointed by Governor Pattison physician to the port of Philadelphia.

U. S. Marine-Hospital Service.—A board of medical officers will meet on Monday, April 16, 1894, in Washington, D. C., for the purpose of examining candidates for appointment to the grade of Assistant-Surgeon in the Marine-Hospital Service. Further information can be obtained from Dr. Walter Wyman, Supervising Surgeon-General of U. S. Marine-Hospital Service, Washington, D. C.

Eleventh International Medical Congress.—A circular of general information has been issued by the Secretary-General of the Eleventh International Medical Congress, to be held at Rome from March 29th to April 5th, copies of which, together with the travelling documents, can no doubt be obtained from the Chairman of the American National Committee, Dr. A. Jacobi, 110 West Thirty-fourth Street, New York.

Billroth, the distinguished surgeon of Vienna, died on February 6th, at the age of sixty-four years, while temporarily absent on a vacation. In 1855 he became

the assistant of Langenbeck in the University of Berlin; in 1859 professor of surgery in the University of Zurich, and in 1867 professor of surgery in the University of Vienna. He was a generous contributor to medical literature, his most notable work being a *Handbook of General and Special Pathology*. He was also one of the editors of the *Archiv für klinische Chirurgie*. His pupils include the names of many distinguished surgeons.

The Nurses' Bureau of the New York Academy of Medicine was opened on Monday, February 5, 1894. Each nurse who registers will be charged a fee of $2 a year for registry, and will be required to have an indorsement by two reputable physicians, who will be written to minutely as to their knowledge of her character and capacity as a nurse. Each time that a nurse is taken out by a patient, the patient will pay a fee of $2 to the bureau for this privilege. When a nurse leaves a case, the physician for whom she has been nursing the case will be written to for minute details as to her management of it, and in many instances the friends of the patient will also be written to. In this way the record of each nurse grows up by accretion, and if a nurse notably fails to perform her duties, she will not be permitted to have the privileges of the bureau.

At first it is proposed to have the rooms open from 8 A.M. to 10 P.M., and certain lists of names will be left with someone in the building over night. As soon as the bureau is running fairly well it will be kept open day and night. A telephone will be put in for the use of the bureau, and the superintendent will be a trained nurse. The work is under the charge of a committee consisting of Drs. S. S. Burt, W. E. Bullard, H. T. Hanks, and R. Van Santvoord.

NEW IDEAS WITH REFERENCE TO TWO WELL-KNOWN OPERATIONS.

BY WHITFIELD WARD, A.M., M.D.,

TEN YEARS SURGEON TO THE METROPOLITAN THROAT HOSPITAL, NEW YORK.

I. THE AMPUTATION OF THE TONSILS.

EXCISION of the tonsils is one of the most frequent operations in the vicinity of the mouth that the surgeon is called upon to perform. Notwithstanding this fact, there are at the present day but few operators who will enter upon its performance without a certain degree of hesitancy or trepidation.

The prime cause of this uneasiness on the part of the surgeon is, as we all know, the danger of alarming hemorrhage. At a meeting of the New York Academy of Medicine in February, 1893, the subject of tonsillar excision was pretty thoroughly discussed. Regarding the extraction of tonsils by means of the knife or guillotine, Dr. Morris J. Asche, under whose auspices the meeting was held, said that it was an extremely dangerous operation. He "did not mean to say that it was a difficult one to perform, but that there might be abnormal arterial distribution causing hemorrhage which could not be controlled." Dr. Asche furthermore stated that danger of serious hemorrhage could be referred to three sources: (1) abnormal distribution of vessels; (2) the venous plexus behind; (3) profuse capillary bleeding. The vessels being enlarged in hypertrophy of the tonsils, they are liable to remain open when divided, and thus cause serious hemorrhage. In the discussion that followed these remarks, although many of the gentlemen did not hold extreme views, yet, on account of the danger of hemorrhage, the majority were inclined to favor the substitution of other and less dangerous methods than the knife or the guillotine for the removal of hypertrophied tonsils.

The principal methods advocated as substitutes for the knife in tonsillotomy are three in number, viz., galvano-puncture, the cautery-snare, and the cold snare. Galvano-puncture, as its name indicates, consists simply in puncturing the enlarged gland with the cautery-needle, endeavoring in the operation to destroy as much as possible of the superabundant tissues.

Those who advocate this method advise that several punctures be made at a single sitting, in order to reduce the number of operations. Under the most favorable auspices, unless, forsooth, the portion to be removed is very small, galvano puncture will require not less than a dozen sittings to produce any decided result.

To those accustomed to make applications with the galvano-cautery, it is unnecessary to state that the pain produced by this method of operation offers quite a serious obstacle to its employment. Another decided objection is the frequency with which abscesses are produced in the punctured glands on account of blind pouches. Again, severe reaction will generally follow each operation, and not only produce much suffering, but also tend to the formation of connective tissue.

With reference to children, this form of operation should never be entertained, not only on account of the pain engendered, but also on account of the length of time required for its performance. When the gland to be removed is of large caliber, galvano-puncture is likewise impracticable, as the patience of the sufferer will have become exhausted long before the operation is completed. It is but fair to state that Dr. Knight, who is in a measure responsible for this method of operation, says that there are only four conditions in which he would resort to galvano-puncture: (1) when one can distinctly recognize vascular anomaly; (2) when the tonsil is deeply buried; (3) when there is hemophilia; (4) when the patient absolutely refuses to be cut. Personally I have had but a single experience with galvano-puncture, the patient, an adult male, falling under the fourth classification of Dr. Knight. When the operation was about half completed the patient stated that he had had quite enough and readily consented to the use of the tonsillotome.

When the snare came into general use several years ago for the extraction of polypoid and other tumors, it was hoped that an instrument had at last been found that would effectually take the place of the tonsillotome.

This hope, however, proved groundless, as practical experience has taught us that the pain attached to the removal of a tonsil with the cold-wire snare is of such an intense character as to preclude its employment. The cautery-snare offers many advantages over the cold wire, and has many advocates. The principal advantages of the former

method are twofold: the operation can be more rapidly performed, and there is much less pain. Several methods of tonsillar reduction other than those tabulated have been from time to time advocated, the principal of which are injections into the body of the gland, and local external applications of caustic or astringent solutions.

At the present time, however, these latter forms of treatment are but little employed.

The only operation which, according to my view, should be resorted to for the removal of hypertrophied tonsils is excision with the tonsillotome.

It is undoubtedly the consensus of opinion of all surgeons that, barring the one danger of hemorrhage, the removal of the tonsils by means of the guillotine is *par excellence* the speediest, the safest, and the most thorough method. In my estimation the dangers of hemorrhage have been greatly overestimated. During sixteen years' experience in both hospital and private practice, in which I have operated upward of five hundred times, I have met with but a single instance of alarming hemorrhage. The bleeding in the case referred to—an out-door dispensary patient—consisted of a slight oozing which continued for several days, the patient being under the care of a homeopath who virtually did nothing. A single application of the galvanocautery stopped the hemorrhage, and the patient, although he had lost a great deal of blood, made a good recovery. Although there are several cases of alarming hemorrhage on record from tonsillotomy, yet there does not seem to be an authenticated case of fatal termination. With regard to abnormal distribution of the carotid, the fear of which has led many to abandon the operation: even though such a condition should prevail, there is no danger of its severance providing the operation be performed properly.

The question that has prompted the writing of this paper is: Can the hemorrhage following tonsillotomy be prevented? If this query can be answered affirmatively the only obstacle to the use of the tonsillotome will be removed, and excision by means of this instrument will be elevated to its proper position in buccal surgery.

About two years ago, yielding to the popular demand, I began to use a 4 per cent. solution of cocain in the form of a spray, from ten to fifteen minutes prior to the operation.

After operating several times on cocainized tonsils, I noticed that the bleeding immediately succeeding the severance of the glands was considerably less than that which it had been my custom to meet with before I had made use of the cocain-spray. After using the spray for about six months I resorted to the use of an 8 per cent. solution, and instead of applying it in the form of a spray, I injected the drug deep into the body of the gland to be removed, allowing an interval of about ten minutes to intervene before operating. The results were beyond my expectations. In a series of twenty cases not more than a dram of blood was lost in any individual case. Those gentlemen who are accustomed to operate in the nasal cavities are thoroughly acquainted with the retractile action of cocain upon the turgid membrane. In cases of small swellings a single application of cocain will oftentimes cause them to disappear entirely for the time being. Another well-known fact is that tissues over which the cocain-solution has been applied will present a blanched appearance for quite a time. This latter effect is the direct result of the peculiar contractile action of cocain upon the plexus of bloodvessels. In the case of excision of the tonsils, cocain undoubtedly contracts the mouths of the vessels in the same manner, and when they are severed holds them so until coagulation takes place. If the tonsil be inspected a few moments after the cocain injection the pallid appearance mentioned with reference to the nasal mucous membrane will likewise be noticeable, although it will not be quite so marked.

Although the cocain when used in the manner indicated proved highly satisfactory, the thought occurred to me that possibly less bleeding would occur after excision of the tonsils if some styptic were to be combined with the cocain and the resulting solution injected in the manner already described. After some little experimentation with different solutions the following formula was used:

℞.—Sol. cocain. hydrochlor. } . āā 10 per cent.
Sol. ferri subsulph. }

Of ten cases in adults experimented upon with this combination, in four the operations were practically bloodless, while in the remainder the bleeding consisted of but a slight oozing from the stump, and this continued but a few moments.

In all of my cases an ordinary hypodermatic syringe was used and the needle inserted successively at several points deeply into the body of the gland and beyond, if possible, the point of severance. The amount of the solution injected was from 30 to 60 drops, the endeavor being made to insert as much as the body would hold.

As a result of these researches I have every reason to believe that this combination of cocain and iron will prove of inestimable value in controlling tonsillar hemorrhage. As I have already shown, the effect of cocain is to constrict the bloodvessels, and if we add to this action the coagulating powers of the ferrous solution it would be but natural to infer that any ordinary bleeding should be entirely controlled. With regard to the

secondary hemorrhages that not infrequently follow tonsillotomy, I have not had a single instance since using the cocain-preparations. My opinion of these accidents is that the sudden shock to the system produced by the operation causes a temporary diminution of the blood-supply to the gland, and that, when the normal circulation is reëstablished, the mouths of the severed vessels not being contracted, alarming hemorrhage is produced.

The successful performance of tonsillotomy depends in a great measure not only upon the style of instrument used, but also upon the manner in which the operation is performed.

Many surgeons recommend the French tonsillotome as the most efficient instrument. There is one decided objection to the French guillotine, and that is, that being provided with a prong or pair of prongs, a preliminary spiking of the gland is necessitated. This transfixion of the hypertrophied gland not only unnecessarily compromises the operation, but seems to drag the gland too far out of its bed, which in unskilful hands endangers a too deep cutting. It is probable that some of the cases of severe hemorrhage on record were produced in this manner. The majority of experts favor the employment of the late Dr. Mackenzie's tonsillotome. One will seldom meet with a tonsil requiring the exhibition of the knife that cannot be thoroughly extracted with this instrument.

If there is not enough of the gland exposed to be included in the ring of the tonsillotome, external pressure by an assistant's hand will generally cause a sufficient protrusion. There is one fault with regard to Mackenzie's tonsillotome that has not hitherto seemed to have been overcome, and that is the knife, being pushed backwards through the body of the gland, will readily slip off the tonsil unless this be snugly encircled in the ring through which the blade plays.

To obviate this difficulty I have designed a special instrument which, it seems to me, should accomplish the purpose for which it was invented.

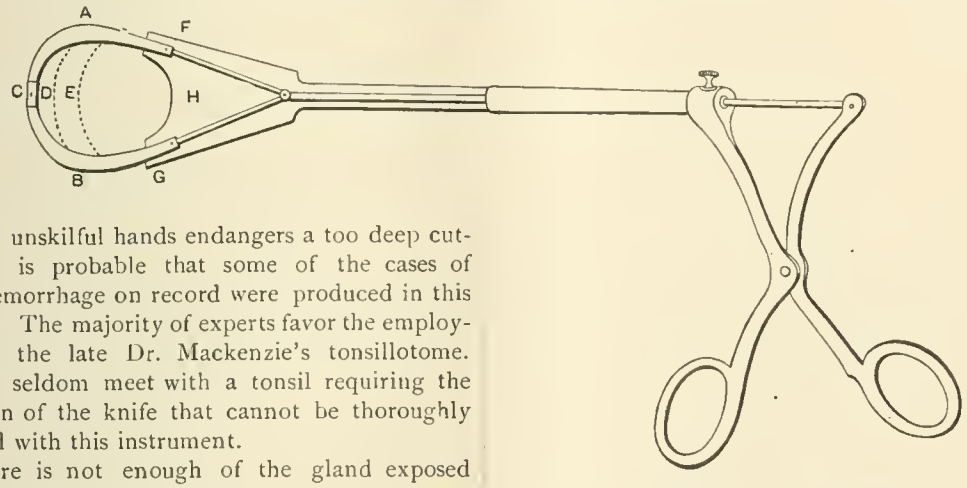
In this instrument the knife-blades, A B, are united at C by a loose joint, the ends, F G, being connected with a central rod to which the handle is attached, in the manner shown in the drawing.

The size of the ring designed to encircle the tonsil is regulated by the movements of the scissors-handle (see dotted lines, D E), the loose joints at F and G playing up and down in slots in the V-shaped framework, H.

The principal feature of this instrument is its adaptability to tonsils of any size. The knife-blade circle, as shown by dotted lines, can be regulated to any desired size either before introduction into the mouth or after the tumor is encircled. Another feature is that when the instrument is operated the blades are compressed laterally as well as drawn from behind forward, thus insuring incision on either side with the backward cutting. This constriction of the gland on either side insures a much better purchase and reduces to a minimum the danger of slipping.

There are several special points that should recommend the adoption of this style of tonsillotome:

1. It is universal in its character—one instrument taking the place of the several different-sized guillotines previously required.



2. Small portions of tonsils can be as readily nipped off as large ones.

3. It is rapid in its action on account of the gland being severed laterally as well as from behind forward.

4. The blades, being turned inwards and sinking at once into the body of the gland, require no guards.

5. Its mechanism is exceedingly simple and cannot readily be disarranged.

The manner in which an enlarged tonsil is removed with this instrument is as follows:

The tonsillotome, being set to the proper size, is to be firmly grasped in the hand on the same side as the tonsil to be excised; the instrument is now introduced, the gland encircled, and forcible pressure exerted upon the handle of the tonsillotome, using the thumb as a lever, the operation being completed as speedily as possible.

The use of a tongue-depressor in tonsillotomy is not only unnecessary but also decidedly detrimental. No matter what style of tonsillotome be used, the operation can best be performed by pressing upon the exposed side of the instrument by the forefinger of the disengaged hand, introduced well into the mouth. The object of this manipulation is to keep the ring well down upon the tonsil until the latter is firmly grasped.

There seems to be much diversity of opinion regarding the amount of tonsil that should be removed. Many surgeons advocate the extraction of as much as possible of the hypertrophied gland. Such advice is not only erroneous but positively harmful, in that it engenders a too deep cutting, and should there chance to be an abnormal distribution of the vessels a dangerous hemorrhage might be the result.

According to my experience the superfluous portion only of the enlarged body should be removed. An excellent plan to follow in this operation is to remove only that portion of the hypertrophied tonsil that juts out beyond the pillars of the fauces.

Regarding the cases selected for operation the surgeon should at all times be governed by common sense. Oftentimes tonsils which in one case would require removal would not require extraction in another, on account of the increased size of the buccal cavity. Again, a diseased condition of the tonsils other than hypertrophy, as, for instance, chronic follicular tonsillitis, oftentimes demands the operation before a permanent cure can be effected.

As a general rule tonsillotomy is demanded when the tonsils offer obstacles to breathing; interfere with speech; prevent full play to the velum; hinder the escape of post-nasal discharges; interrupt deglutition; and produce deafness or other aural difficulty.

In the writing of this article it has been my earnest endeavor to demonstrate that the oft-neglected operation of tonsillotomy should be performed by the surgeon without the slightest degree of hesitation, provided the subjoined precepts be observed:

1. The proper selection of the cases for operation.
2. The injection of cocain and iron.
3. The selection of the proper instrument.
4. The proper performance of the several steps of the operation.

II. The Amputation of the Uvula.

The amputation of an elongated uvula, although generally considered an exceedingly simple operation, oftentimes requires the exhibition of a great amount of skill.

In a paper that I contributed several years ago to the columns of the *American Journal of the Medical Sciences*, I had the pleasure of directing the attention of the medical profession to the importance of the uvula from a physiologic standpoint, and to the danger of injuring the voice by a too free exhibition of the knife.

In order to be thoroughly understood by those not acquainted with the subject, it will be necessary to give a brief *résumé* of the subject in the present paper.

The tone-waves that are created by the vibratory action of the vocal bands pursue three different courses in their journey from the body, viz.: through the mouth; through the nasal organs; and through the mouth and nose combined. The direction that each wave takes depends entirely upon its position in the voice-register. During the vocalization of sounds that pass through the nose alone, the velum rests throughout its entire extent upon the dorsum of the tongue, thus shutting off all communication between the cavities of the mouth and posterior nares. During the intonation of sounds that pass through the mouth alone, the soft palate is pressed tightly against the pharynx, the tone-waves thus finding an exit only by the mouth.

During the singing of tones that issue in the same degree from both nose and mouth, the pendulous velum is poised in the back of the mouth at an equal distance from the tongue and the pharyngeal wall. When the velum is pressed against the back of the tongue the uvula lies dormant upon the surface of the lingual organ; when, however, the palate begins to rise, the uvula, which has hitherto been inactive, stretches itself suddenly, becoming an active participant. As the velum recedes from the tongue, the attached uvula rises and accompanies it in its journey upward, until finally its tip only touches the back of the lingual organ; when this point is reached, if the uvula is of the normal size, the velum occupies the median line of the mouth—that is to say, it is equidistant from the tongue and the pharynx. At about this time, as the vocalist proceeds in the ascending scale, the uvula will be seen to be drawn speedily upward, producing a prominence on the posterior surface of the soft palate. This eminence increases in size as the uvula is drawn upward, and reaches its maximum when the latter body has retreated to its fullest extent. The function of this posterior palatine eminence is to act as a support to the velum by impinging against the posterior pharyngeal wall.

The function of the uvula, then, is to act as a prop to the velum, using the tongue as a basis of support during the rendition of the lower half of the register, and the pharynx during the production of the upper half. If the velum were to be deprived of this support, an undue amount of vibratory action would be superinduced by the escaping tone-waves, which would impart an abnormal amount of

tremulousness to the voice. When the uvula is abnormally long it will be utterly impossible for the velum to perform the movements described in a proper manner, on account of the extra weight imposed by the elongated body.

The amputation of the excessive portion of the uvula then becomes a paramount necessity. We come now to a consideration of a highly important point, the determining of the amount of an elongated uvula that should be removed. The settlement of this point is oftentimes a difficult matter, as a uvula that might be of a sufficient length to interfere with the vocalatory efforts of one individual, would be of the proper dimensions in another person, on account of the difference in the size of the cavity of the mouth. An excellent rule to guide the surgeon in the settlement of this point is to gently depress the tongue, allowing it to arch slightly at the base, at the same time instructing the patient to relax his velum. If the uvula is of normal length its tip will just touch the arched portion of the dorsum of the tongue; but if, on the contrary, it is elongated, the superabundant portion will lie flaccid upon the lingual organ. With reference to the style of instrument used in amputating the uvula I would say a word. It would naturally seem to the uninitiated that the guillotine would be the simplest and most effective instrument with which to perform this simple operation. Such, indeed, would be the fact if the patient could always be depended upon to hold the velum perfectly quiet. But unfortunately the reverse of this statement is the rule, the velum being prone to change its position upon the slightest provocation; and should this accident happen at the instant the knife is sprung, an undue amount may be amputated, and the important function of the organ destroyed. I have seen this result follow the use of the uvulatome many times, and doubtless other surgeons have had the same experience. The manner in which the amputation of the uvula is generally performed is as follows: The body is grasped just below the point of severance by means of an ordinary pair of spring-forceps held in one hand, and the excessive portion is snipped off through the agency of a pair of long curved scissors held in the disengaged hand.

There are several decided objections to this method of operation. In the first place, the assistance of the patient is always required to handle the spatula. In many cases, on account of age, nervousness, or other cause, the aid of the patient cannot be relied upon. In the second place, it is difficult to gauge the proper amount to be severed, because the dragging of the body forward with the forceps has a tendency to lengthen it. Again, on account of the pulling forward of the body to be amputated, the stump left after the operation is inclined to be very irregular.

I have lately devised an instrument which I feel certain will obviate these difficulties.

This device consists essentially of two distinct instruments united, namely, forceps and scissors —the arms of the latter being attached to a rod by which it can be operated forward and backward. In manipulating this form of uvulatome the rod is pulled out to its fullest extent, which closes the scissors; the curved handles of the forceps is then grasped, the thumb resting on the thumb-piece of the rod. The uvula is now seized at the point of severance by the jaws of the forceps and clipped by pushing the rod home. The scissors-portion of the instrument is made to rapidly open and close by the revolution of the handles around a curve located on either arm of the forceps. The advantages of this instrument can be seen at a glance:

1. But one hand being necessary to operate it, the other is left free to operate the spatula.

2. The surgeon can see what he is doing at all stages of the operation, and need make no mistake.

3. The stump will be perfectly clean and even.

PHYSICAL EDUCATION.

By RANDOLPH FARIES, M.D.,
of Philadelphia;
Director of Physical Education in the University of Pennsylvania.

Physical education is a subject about which a great deal is being written. This is due to the fact that within the last ten years all the leading colleges, academies, and schools for men, women, and children have paid greater attention to the ever-increasing demand for knowledge. Realizing that the human mechanism must be in perfect order to accomplish the best mental results, these institutions have seen the necessity for making the structures well balanced in body and mind. Numerous are the statistics that certify to the good results that physical education has accomplished. Yet one must not imagine for a moment that physical education will apply to all constitutions; it will not, as I hope to show a little later. Education, properly speaking, has to do with everything that will develop any part of the human frame, mentally, morally, physically, or spiritually. In using the word education, I might more properly have said every department of the being Man, in the generic sense, because no one department can be educated unless some one or other department suffers. Do we not see thousands of men and women who forget all about their spiritual nature, while their mental nature predominates over worldly things—beings who seem to have lost all traces of spiritual instinct, although they have wonderful mental capacity and physical development, becom-

ing in fact monstrosities, because there is an utter lack of equilibrium between the parts of their being which depend for their support upon the coördination of every part.

The majority of schools for physical education are empiric because those having charge of them know absolutely nothing about the construction of the human frame and the laws governing the different physiologic phenomena taking place therein. I venture to say that it has never entered the minds of scores of teachers of physical education that many of their pupils are those who, in the first place, do not need physical work, but who need absolute rest, and this rest must frequently extend over a long period. Those who are familiar with the "rest-cure" of Dr. S. Weir Mitchell well know how essential is rest for thousands of persons. Ignorance of a want of rest to begin with—and I mean absolute rest in bed in some cases—has led many a man to his grave who has thought to find a panacea in physical culture. Movements are a most potent means for affecting the body, as potent as drugs, and is it any wonder that so many men die with diseases of the lungs, the heart, or the nervous system, and their associates, when these movements are prescribed by an empiric? Imagine a man practising medicine without a degree, and how much faith would any sensible patient have in him. Quackery is practised every day in physical education, and in many ways; for example, men who have lung-troubles, or a great predisposition thereto, are prescribed movements with chest-weights (because these men usually have hollow, narrow, and contracted chests), which will exercise the muscles covering the chest and back, and the movement is frequently too violent for the pulmonary condition, no matter how slight it may be, the result being an aggravation of the trouble instead of its alleviation. In another case a person who has cardiac palpitation, or it may be valvular disease, is told to take a light run; a third is told to use the high pulley and is shown certain movements for the lower or lumbar region of the spinal column, in order to develop certain muscles there. In this region will be found the kidneys, and they are surrounded on all sides by muscles and bound down by tissue. Imagine a man being told to perform such a movement for a weak back, when the weakness he complained of was due to disease of these organs. It amounts to just the same thing as telling a person who has worked too hard mentally to keep on working; in both cases the trouble is aggravated, and anyone can see the folly of such a course.

How many persons who think of taking a systematic course of physical work ask themselves the following questions: Do I need any work at all? If I need work, what kind do I need? How much do I need? What is the most proper time for exercising? How am I to know whether it is benefiting me or not? What is the state of my constitution? Are there any accessory conditions I must observe, and what are they?

I have already shown why it is important for a person who anticipates taking a course in physical work to undergo a rigid medical examination at the outset, but it will not be amiss for me to strengthen the importance of this by saying that in cases in which disease of the heart, lungs, or kidneys exists, there is danger of causing sudden death by the use of apparatus. When exercise is doing good the resulting phenomena will be as follows: Increase in appetite; regularity of heart-impulse; increased pulmonary capacity; bright color of skin; increase in size and tone of muscles; increase in bodily weight (training excepted); and good sleep. If it be causing harm we have the following symptoms: Appetite impaired or lost; irregular impulse of heart; pallor of skin; decrease in size and tone of muscles; loss of weight; headache; nervousness, causing sleeplessness; slight fever, which resembles typhoid; and a dry throat, at times followed by a slight cough, which not infrequently leads to bronchial or pulmonary complaint.

Every movement of the body is simply a physical expression of a nervous impression produced either by the brain or spinal cord, and in all voluntary movements the primary impulse starts from the brain; hence we see that movements develop not only physical powers but cerebral powers as well. If a person wishes to arrive at a healthful development of his body, he must begin with the primitive type and gradually advance in alphabetic order, just as a child does when it is taught to read. A proper coördination of any movement depends upon a proper state of the mind; hence we see that if the mental faculties are not in a condition of stability, the body as a whole is not in harmonious accord with the mind. If an exercise is to be correctly performed it must be based upon the temperament and character of the person who is about to perform it, so that each department of his whole being will work in harmony with its fellow-departments; it is in this way alone that the human organism will become capable of perfect development, thus bringing its several parts into perfect harmony.

There is a limit to the powers of every being upon earth, and with man it will be found that this limit is fixed by his bodily powers, as well as by his mental faculties. If a movement be applied incorrectly, the faculty of an individual will not infrequently be perverted, and therefore we see that such a movement is injurious, and detrimental to symmetric development. The over-development of one part is always accompanied by a corresponding weakness

in its sister part. We all know how very helpless the left hand of myriads of persons is. This is very easily explained. In our bodies will be found a certain quantity of blood, about one-twelfth or one-fourteenth the body weight; exercise increases the flow of blood to a part; we exercise our right arm more than our left and more blood goes to it. We continue to use it, and the bloodvessels being nothing more than elastic tubes, expand and after awhile their caliber becomes permanently larger, and as fluids flow in the direction of least resistance, a greater quantity of blood goes to the right arm than to the left, and the left suffers to a greater or less extent; the result being that the left arm grows smaller according to its decrease in blood-supply, while the right grows larger in proportion to the amount of blood it receives. This principle applies not only to the upper extremities, but to all parts of the body. Symmetry of body in its broadest sense, *i. e.*, spiritually, mentally, morally, socially, physically, and politically, is the great aim of all properly prescribed exercise, because healthful power is due to a simultaneous action of all parts of the body, and to produce power and motion in such a way that the maximum force may be attained, it must coöperate simultaneously in every part.

From this we see that the terms physical force and perfect health are correlative, as both depend upon harmony among all parts of the human organism. If one will begin with the simplest kind of exercise and gradually advance, he will be able in due time to accomplish feats that were well-nigh impossible at first, and without danger of jeopardizing his constitution, as he will acquire an instinctive knowledge of what he is capable of undertaking. It is when one does not regard this knowledge that disease is produced.

If we classify the different phenomena that take place in our bodies, we may put them under three heads: mechanical, chemic, and dynamic. The first include circulation, deglutition, mastication, respiration, etc.; the second, nutrition, sanguification, secretion, excretion, assimilation, and the like; and the last are merely evidences of the mind which we see in our intellectual and moral powers. Every vital act, no matter how small or how great it may be, is produced under the combined influence of these three classes of phenomena, and it is by their conjoint action that a perfect organization characterizes itself; moreover, when this action is disturbed, an alteration in function takes place, and this in nearly every case is followed by disease. If the harmony of any one part be deranged it may be reëstablished by increasing the vital activity of the part, and this can be accomplished more perfectly by exciting the blood-current by exercise than in any other way, thus supplying a natural means, which is physiologic in nature, instead of using drugs that are therapeutic in their nature, and are used to change pathologic to physiologic conditions. Many persons laugh when they are shown free movements, because these movements are so simple; but it is frequently from their simplicity that the good is derived which one receives.

Variety of exercise is a most important factor, in bodily as well as in mental work, because by changing from one form of exercise to another, different sets or groups of muscles are used, while others are at rest, and in this way there is less danger of overworking the body. The special kind of exercise one usually needs can only be mapped out by a physician after making a most thorough medical examination. Strict attention should be paid to the prescribed course and a faithful pursuance of it until the body becomes symmetric.

Physical culture for women is most beneficial, and nearly every woman needs it in a greater or less degree; yet there are some for whom it would be certain death, and especially so when prescribed by an empiric. Women's occupations are more sedentary and their exercise must be simpler and lighter than that prescribed for men, because their muscles are weaker. As a rule one will find that women are very weak and poorly developed about the arms, back, and chest, while their lower extremities are well developed; so much so that the figure is anything but symmetric. Exercises can be prescribed that will change, strengthen, and develop the arms, back, and chest, giving as a final result a symmetric figure. More care is neccssary in prescribing exercise for women, because by making inquiry into the heredity of most women, we find that their mothers, grandmothers, and great-grandmothers have never taken any exercise whatsoever; but with men such is not the case, and we find that for generations exercise of some sort or other has been indulged in by the father. If persons knew a little more about the scientific care of themselves, the tendency to disease would be greatly diminished, and in diminishing this tendency I am sure there would be an increase in their moral and spiritual attributes. I have seen many a person changed, by observing scientific rules while in training for an athletic contest, from a state of immorality to one of noble-mindedness; and I feel sure that this was due to the fact that the training, which caused the elimination of certain waste materials which are bodily depressants, brought new life to him, thus enabling him to develop qualities which were blunted or made dormant by the retention of these materials.

Persons in exercising should always remember that the exercise indulged in should invariably keep pace with one's strength. A disregard of this will

unquestionably, sooner or later, produce disease of some kind. Over-ambition and anxiety have sent many strong healthy men and women to premature graves. I venture to say that nine-tenths of all persons who take exercise, rarely if ever ask themselves the questions I have enumerated, and even when such has been the case, have never followed a prescribed course under the care of a specialist. If those who need a course of exercise would consult an experienced physician, just as they do when attacked by disease, there would not be the predisposition to disease caused by the thousand and one apparatuses in existence.

THE PROGNOSTIC SIGNIFICANCE OF TUBE-CASTS.[1]

By I. N. DANFORTH, A.M., M.D.,
PROFESSOR OF CLINICAL MEDICINE IN NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, AND OF RENAL DISEASES IN NORTHWESTERN UNIVERSITY MEDICAL SCHOOL FOR WOMEN.

No physician in active practice need be reminded of the fact that, although every physician will admit the desirability of having data from which he can predict the probable result in a given case of chronic nephritis, as yet no such reliable data exist.

Without stopping to discuss the general symptoms of chronic nephritis, for the purpose of estimating their prognostic significance, I will pass at once to the subject before us, and announce my conviction that the study of tube-casts furnishes the best basis for a reliable prognosis in any case of inflammation of the renal parenchyma.

This brings us to the first practical question, namely: What do we mean by "tube-casts"? The answer is very simple: Tube-casts are cylindriform bodies formed in the renal tubules, accurately representing the caliber and condition of the tubules in which they are found. This is equivalent to saying that the casts disclose the pathologic status of the tubules, and that by studying the casts from time to time, the progress of a given case toward recovery, or the reverse, may be followed.

An important preliminary to the study of the prognostic indications of tube-casts is a recognition of the varieties and their proper grouping or classification. Obviously the classification of tube-casts should be based upon their pathologic derivation, if this can be determined, as I think it can in all cases. A practical study of tube-casts, in connection with other clinical manifestions of renal diseases, will convince the observer, first, that all tube-casts are the result of some form or some degree of nephritis; second, that certain casts are the product of, and therefore denote, non-exudative inflammation, which is nothing more or less than a simple catarrhal inflammation as limited and defined by Ziegler; third, that certain other casts are the product of, and therefore denote, exudative or croupous inflammation; fourth, that each class has its varieties, which are easily recognized by characteristic and uniform peculiarities of structure, and that these peculiarities of structure are associated with, and therefore denote, characteristic and uniform pathologic lesions. Consequently I am justified in assuming and asserting that the tube-cast, if properly studied and understood, sustains the most important relation to prognosis. On pathologic grounds I suggest the following classification:

VARIETIES OF TUBE-CASTS.

1. Casts of non-exudative origin.
   - *a.* Mucin-casts (or mucous casts).
   - *b.* Mucin-casts enclosing cell-forms.
   - *c.* Mucin-casts enclosing crystals.
2. Exudative casts (fibrinous casts).
   - *a.* Hyaline casts.
   - *b.* Waxy or amyloid casts.
   - *c.* Blood-casts.
   - *d.* Epithelial casts { small. / large.
   - *e.* Granular casts { small. / large.
   - *f.* Fatty casts { small. / large.

The prognostic inferences to be derived from casts are based:

First. On the origin of casts, whether non-exudative or exudative—that is, whether mucous or fibrinous. If the former, it establishes the fact that the lesion is a catarrhal one only, and therefore at the worst is limited to a cloudy swelling of the renal epithelium, a condition that always warrants a favorable prognosis; if the latter, it warrants the conclusion that a true croupous inflammation, with characteristic exudation, is present, and the prognosis must be reserved until after mature and deliberate investigation has been made.

The general professional opinion is that these mucous casts are practically of no importance so far as regards prognosis or treatment; but it is nevertheless true that they constitute a certain indication of the approach of true chronic nephritis, and it is only a question of time when catarrhal nephritis, as indicated by mucous casts, will become croupous or exudative nephritis, with characteristic hyaline casts.

The general professional opinion is that hyaline casts are scarcely less than a death-sentence—at least that recovery is very unlikely to occur after true fibrinous casts have appeared. But my experience during the past ten years fully warrants me in asserting that recovery is not uncommon, and

[1] The Address in Medicine before the Illinois State Medical Society, at its meeting in Chicago, May, 1893.

ought not to be unexpected after the presence of hyaline casts denotes the development of a true croupous nephritis.

Second. The prognostic significance of casts depends upon their size, or diameter. This applies to a certain extent to all casts, but more particularly to the epithelial and fatty varieties. In my classification I have included "small" and "large" casts. The small casts are formed in tubules that are not yet denuded of their epithelium, and therefore are not essentially damaged by degenerative changes. They point to the fact that the caliber of the tubes has not been increased by exuviation of their epithelium, and hence they *must* have been formed in tubules whose functional capacity is not materially diminished. Such casts warrant a fairly favorable prognosis, as it is not unreasonable to expect that tubules that still retain their specialized functional cells, although somewhat swollen and cloudy, may recover both their structural and functional integrity, and experience abundantly confirms the foregoing prophecy. On the other hand, casts of large diameter originate in tubules from which the epithelium has disappeared, either in flakes or patches, by a process of exuviation, or else singly, or by twos and threes, on account of degenerative changes. This indicates a condition of great gravity, and always requires an unfavorable prognosis, because it furnishes infallible proof that tubules so denuded are no longer endowed with functional power. But if large and small casts occur in association, and if the small casts predominate, thus indicating that the majority of the tubules still retain their epithelium, a possible recovery may be predicated.

Third. The prognostic significance of casts depends upon their regularity or symmetry. A straight symmetrical cast, of uniform size and appearance, must have been formed in a tube not yet distorted and twisted out of shape by the encroachment of pathologic connective tissue. It indicates, therefore, the absence of cirrhotic change, and certainly shows that the tubes in which the casts in question were formed have not been damaged by pathologic intertubal deposit. On the other hand, if the cast is distorted, twisted, and asymmetrical, it unerringly points to the fact that it was formed in a distorted, twisted, and asymmetric tube—a tube environed and strangulated by connective tissue, abnormal as to locality, quantity, and behavior. In other words, it proves that the process of cirrhosis is well advanced and that the kidney is damaged beyond any possible recovery. Treatment may retard the progress of the disease, but the ultimate history of the case is fixed beyond recall. In all cases of renal cirrhosis—especially those of rheumatic or gouty origin—this point is an exceedingly important one, as the prognosis must necessarily depend upon the degree of renal cirrhosis present, and I know of no way to decide the matter except by a microscopic study of the tube-casts; and this, in my belief, does furnish an accurate and reliable basis for a medical judgment far superior to any opinion based upon general symptoms only.

So, also, in the late stage of tubal nephritis, the roughened, decayed, or "nibbled" appearance of the casts shows conclusively that the tubes wherein they were formed are undergoing advanced fatty degeneration, and the case must be regarded as utterly hopeless.

Fourth. The prognostic significance of casts depends upon their structure or constitution. It is probable that all except mucous casts are primarily fibrinous; that is, are formed by the union and coagulation of the fibrin-factors. Without stopping to argue this proposition I shall assume it to be true, merely adding that it is an opinion that would not be universally accepted. The contents or structural factors of casts vary greatly, and each different factor, or group of factors, tells its own story.

The hyaline or structureless cast denotes croupous inflammation in the early stage, before degenerative changes have commenced, and, in the absence of other and more portentous casts, warrants a favorable prognosis.

The hyaline blood-cast, or the hyaline cast loaded with blood-globules, denotes a renal hyperemia so intense that some of the delicate renal vessels have been ruptured, and that hemorrhage has occurred. Of course this proves the presence of an acute process, although it may be an acute exacerbation in the course of a chronic lesion. If the former only, a favorable prognosis is warranted; if the latter, the prognosis will, of course, be very grave.

The import of epithelial casts—that is, the hyaline casts loaded with renal epithelia—will depend very much upon the condition of the cells. If they have undergone no essential pathologic change, but are simply exfoliated cells entangled in the cast, a favorable prognosis is warranted on theoretic and practical grounds. Recoveries are by no means uncommon under such circumstances. But if the contained epithelia have undergone, or are in the incipient stage of, fatty degeneration, the prognosis is always grave. In fact, the gravity of the case is in exact proportion to the extent of fatty change shown by the renal epithelium. Of course, I am not now taking into account cardiac or other complications, as it is the purpose of this paper to deal with tube-casts and their relations to prognosis only.

When the tube-casts become granular, or distinctly fatty, the prognosis has at least the positive character of certainty. It is certainly, positively, and unerringly bad. The fatal result may still be

far off—in fact, partial recovery may take place—but it will prove nothing more than a delusive calm, sure to be followed by a fatal outbreak sooner or later.

Fifth. The prognostic significance of tube-casts depends upon their relative numerical proportion. If hyaline and epithelial casts exist together, but with a predominance of hyaline casts, the prognosis is less grave than when epithelial casts predominate. If fatty and epithelial casts exist together, and the former predominate, the case is in more immediate danger than it would be if the conditions were reversed. This rule holds good as regards all other combinations of casts as they appear in clinical experience.

I hold, therefore, that the systematic study of tube-casts furnishes the most satisfactory and reliable groundwork for prognostic conclusions in each and every case of chronic nephritis. I do not undervalue other symptoms or indications; I only claim that the prognostic significance of casts has been greatly undervalued, and I ask for them a proper place in future prognostic calculations.

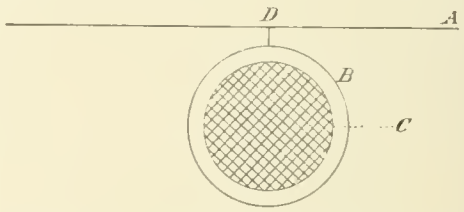
ATHEROMA.

By DOUGLASS W. MONTGOMERY, M.D.,
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; CONSULTING PHYSICIAN FOR DISEASES OF THE SKIN, AND FOR PATHOLOGY, GERMAN HOSPITAL.

Although operations for the removal of atheromata may be followed by disease of the wound, such as erysipelas, usually the healing takes place so quickly that surgeons have been again and again surprised at the good results. This was especially noteworthy in the old days, when cleanliness was not so customary as at present. But men are still found boasting that they can make large wounds in the scalp without anything serious following, and with remarkably rapid healing; the truth is they have made a mere scratch. It is a good thing to tell of one's happy results, but, in the present case, it would be more to the point if the real reason of the rapid return to the normal were given, instead of attributing it to skill, to the sharpness of the knife, or to the use of any particular form of antiseptic.

The real reason for the rapid healing can easily be seen if the pathologic anatomy of the affection be for a moment thought of. Let the line *A* represent the surface of the skin, the circle *B* stand for the true connective-tissue capsule of the wen, and the circle *C* represent the hard, glazed, horny capsule of epithelium covering the central detritus. It is this inner circle that has given rise to misunderstanding, for men frequently teach that this is the outside connective-tissue covering of the tumor, whereas the real connective-tissue capsule is represented by the outer circle.

The wen must be regarded as a globular cavity of connective tissue, lined with flat, stratified epithelium; it is, in fact, a piece of involuted skin, the connection of which with the outer surface of the body has become obliterated. The epithelium of this piece of skin is being continually thrown off, but instead of being shed, as it is on the outer surface of the body, it is heaped up in the center, and there forms a mass of detritus.



In operating, an incision is made over the most prominent part of the tumor, and an ivory-like, slippery ball is exposed, which readily pops out through the slit. There usually is, as in all scalp-wounds, considerable bleeding.

Now what has the operator done? The slit that he has made in exposing the ivory-like ball is positively the only wound that exists. The sac out of which he has pressed the ball is not a raw surface, but a piece of epithelium dipped down into the skin, and as sound and healthy as the skin on the back of the patient's hand, and ready, like that of the hand, to continue to throw off its epithelium, which, in time, will form a new ball. Those who suppose that the inner surface of this sac is raw will say that it is red and moist, and that surfaces covered with epithelium are neither red nor moist. This surface is, indeed, both red and moist, because it is the rete Malpighii, the covering of the ball being formed by the more completely keratinized cells of the granular and horny layers.

My attention was first called to the anatomy of a wen by examining a section of the wall of one of these glistening balls, and finding it not connective tissue lined internally with epithelial cells, but constituted entirely of epithelium, with some layers of flattened nucleated epithelial cells forming its external covering. That settled its nature, and I saw that an operation, to be radical, must go outside the connective-tissue capsule. But whether or not it is desirable to do this radical operation is another story, for the real connective-tissue capsule is, as Cruveilhier long ago showed,[1] very delicate, and would be very difficult to dissect out. On the other hand, the slow refilling of the sac is a comparatively unimportant matter.

After evacuating the cavity the farce of curetting

[1] Cruveilhier: Traité d'Anatomie Path. gén., tome iii, p. 346. Quoted by Virchow, Die krankhaften Geschwülste, Band i, S. 227.

it or swabbing it out with a caustic solution, is sometimes indulged in. Except in cases in which the horny capsule adheres to its base, curetting does harm by wounding the otherwise intact wall.

The term "atheroma" is to be preferred to that of sebaceous cyst, because the latter term would indicate that all such tumors are retention-cysts of sebaceous glands, and this is not so. Probably the vast majority of these tumors are formed by embryonic displacements of external epithelium. At all events a cavity is formed, lined with epithelium. The word atheroma, meaning literally, *porridge*, and only having reference to the appearance of the central mass of detritus, indicates no theory, and is therefore unobjectionable. The term "wen," the original meaning of which is never taken into account, is possibly even better than atheroma, because it is applied to no other pathologic condition.

The diagnosis of atheroma is usually easy, but sometimes the matter is serious.

In 1888 an interesting case came under the observation of Dr. J. H. Stallard, who removed a growth from the scalp of a woman of fifty-six years of age, which before operating he supposed to be a wen, but which upon incision did not shell out readily as wens usually do. He examined a piece of the tissue and found it was an epithelioma, and a second, more thorough operation was performed two days after the first. About one year afterward an ulcerating surface appeared at the site of the operation, for which the patient practically did nothing up to the time when I first saw her, on January 15, 1890. There was then a large raw surface over the left parietal bone, about three inches long by one inch broad, with an attempt here and there at cicatrization. The edges were high, rounded, smooth, bald elevations of a deep-red color, and very hard—an exaggeration of the comparatively low, rolled edges frequently seen in rodent ulcer. It was easy to imagine how closely the original growth must have simulated an atheroma. A piece of the rolled edge was cut out for examination and found to be an epithelioma in which the epithelial cells were remarkably well preserved.

I saw the case but once, being one of several physicians called to determine positively whether it was carcinoma or not, with the understanding that if found to be carcinomatous it was to be let alone. The patient died about twenty months after this with symptoms indicating implication of the brain.

The Eighth International Congress of Ophthalmology is to be held at Edinburgh during the coming August.

Prausnitz has been made Extraordinary Professor of Hygiene in the University of Gratz.

ORIGINAL ADDRESS.

MEMORIAL ADDRESS IN HONOR OF DR. EPHRAIM McDOWELL.[1]

BY L. S. McMURTRY, M.D.,
OF LOUISVILLE, KY.

AT the last annual meeting of this Association a resolution was adopted establishing the custom of having some Fellow prepare for each annual meeting a memorial address commemorating some deceased eminent Southern surgeon or gynecologist, and appointing for this meeting an address upon Ephraim McDowell. In accordance with its provisions I have the honor to appear before you on this occasion.

It would seem almost a work of supererogation to submit an elaborate biographic sketch of McDowell after the very complete accounts of his life and labors by the late Prof. Samuel D. Gross and the late Dr. John D. Jackson. Yet, I presume that no one will for a moment question the good taste and wisdom of perpetuating in our volumes of *Transactions* the names and deeds of those eminent Southern surgeons who did so much to lay the foundation in America and the whole world for the present splendid system of surgery and gynecology. This galaxy of illustrious names would be incomplete without that of McDowell, the "Father of Ovariotomy" and the pioneer in abdominal surgery.

In 1852, twenty-two years after the death of Ephraim McDowell, Professor Gross, in his celebrated report on Kentucky Surgery to the Kentucky State Medical Society, presented a sketch of the life of this eminent surgeon, with a detailed account of his original surgical work. This sketch was subsequently incorporated in Gross' *American Medical Biography*.[2] In this memoir, Professor Gross formally set forth McDowell's claims as the originator, by successful accomplishment of the radical cure of ovarian tumors by abdominal section. In 1879, at the dedication of the monument erected by the Kentucky State Medical Society over the grave of McDowell at Danville, Kentucky, Professor Gross delivered an elaborate memorial oration, in which he reviewed his former sketch and paid fitting tribute to McDowell's memory, silencing forever the criticisms and claims of certain English surgeons who endeavored to claim for others the honor and credit justly due McDowell. This occasion was made imposing by the Kentucky State Medical Society, and, by the monument erected and the memorial volume published, the name and fame of McDowell were established as the valued and cherished heritage of American surgery. I had the honor on that occasion to introduce Professor Gross (if I may use the word in its restricted sense), and shall never forget the eloquence and enthusiasm of the Nestor of American Surgery as he depicted in thrilling words the achievements of the subject of his oration. Upon the platform were seated the Governor, the Secretary of State, and other dignitaries of the State of Kentucky; the President of the American Medical Association (Dr. Lewis A. Sayre); the venerable Dr. Gilman Kimball, of Lowell, Mass. (who had then performed ovariotomy almost three hun-

[2] Published by Lindsay & Blakiston, of Philadelphia, in 1861.

dred times), and many other distinguished American surgeons, with a large convention of the Kentucky State Medical Society, and an audience of cultivated people. Among the letters read on the occasion, paying tribute to McDowell's worth and fame, were those of Sir Spencer Wells and Mr. Thomas Bryant, of England; Fordyce Barker, T. Gaillard Thomas, Oliver Wendell Holmes, T. G. Richardson, Theophilus Parvin, and other distinguished Americans.

In 1872, the late Dr. John D. Jackson, of Danville, Kentucky, published a biographic sketch[1] of Ephraim McDowell. Dr. Jackson was at that time actively engaged in medical practice in the town in which McDowell had lived and labored, and among his friends and colleagues were those who had known the first ovariotomist personally, as well as a number of his relatives by blood. In Dr. Jackson's sketch he states that he was able, by conversation with numerous contemporaries of McDowell, to verify the statements contained in Dr. Gross' memoir, thus giving additional confirmation to the discriminating observation of Dr. Gross as a biographer. Having been reared and educated in Danville, and having for several years practised medicine there, I can also attest the fidelity and care with which Dr. Jackson traced the personal characteristics and professional work of the subject of this sketch.

Ephraim McDowell was born in Rockbridge County, Va., on the 11th day of March, 1771. His ancestors removed from Scotland to the valley of Virginia in 1737. His mother's maiden name was Sarah McClung, the name indicating that she, too, was of Scotch ancestry. McDowell's father was prominent in political life in Virginia, and a member of the Legislature of that State; in 1772 he came as a land commissioner to Kentucky (which was then a portion of Virginia), and soon afterward removed his family to Danville. He was afterward appointed judge of the District Court of Kentucky. Ephraim McDowell received his early education at a classic seminary at Georgetown, Kentucky, and then went to Staunton, Virginia, to enter the office of Dr. Humphreys, of that place, as a medical student. Of Dr. Humphreys little is known, save that he was a graduate of the University of Edinburgh, and a man of ability. In 1793, McDowell went to Scotland to attend lectures at the University of Edinburgh. At the same time Dr. Samuel Brown, a member of the first corps of lecturers at the Transylvania University at Lexington, Kentucky, and Drs. Hosack and Davidge, of New York, were attending the great Scottish University. Young McDowell remained in Edinburgh during the session of 1793–94, but did not receive the degree of M.D. As far as we know, the degree of M.D. was not conferred upon him until 1823, when, entirely unsolicited on his part, the University of Maryland conferred upon him the honorary degree of M.D. The Medical Society of Philadelphia, at the time the most distinguished of its kind in this country, sent him its diploma in 1807, two years before he performed his first ovariotomy. Thus it will be seen that McDowell had attained national distinction as a surgeon before he undertook the work that has made his name famous.

While in attendance at the University of Edinburgh, McDowell attended the private instructions of John Bell, the most able and eloquent of the Scotch surgeons of his day. That portion of Mr. Bell's course in which he lectured upon the disease of the ovaries and depicted the hopeless fate to which their victims were condemned made a powerful impression upon its auditor. Indeed, McDowell afterward stated that the principles and suggestions at this time enunciated by his master impelled him sixteen years afterward to attempt what was considered an impossibility. In 1795 McDowell returned to his home in Danville, then a small village in the Western wilderness, and entered upon the practice of his profession. Being a man of classic education, coming from the most famous medical school of the world, he soon easily assumed the first professional position in his locality, and within a few years he became known throughout all the Western and Southern States as the first surgeon of this entire part of the country. Indeed, until Dr. Benjamin W. Dudley, of Lexington, Ky., came upon the field, McDowell stood without one to dispute his position as the most eminent surgeon west of the Alleghenies. During this time his practice extended in every direction, persons coming to him from all the neighboring States; he frequently made long journeys on horseback to operate upon persons whose condition would not permit them to visit him at his home. So far as is known, he was in the habit of performing every surgical operation then practised. In lithotomy he was especially successful, and, up to 1828, was known to have operated twenty-two times without a single death. He operated many times for strangulated hernia, and did successfully various amputations and other operations, including tracheotomy.

In 1809, fourteen years after he had begun the practice of his profession, he was sent for to see Mrs. Crawford, residing in Greene County, Kentucky, some sixty miles from Danville. McDowell found her to be the subject of an ovarian tumor, which was rapidly growing and hastening to a fatal termination. In the language of Gross: "After a most thorough and critical examination, Dr. McDowell informed his patient, a woman of unusual courage and strength of mind, that the only chance for relief was the excision of the diseased mass. He explained to her, with great clearness and fidelity, the nature and hazard of the operation; he told her that he had never performed it, but that he was ready, if she were willing, to undertake it, and risk his reputation upon the issue, adding that it was an experiment, but an experiment well worthy of trial." At the close of the interview Mrs. Crawford declared that any mode of death, suicide excepted, was preferable to the slow death which she was undergoing and that she would submit to any operation which held out even a remote prospect of relief. Mrs. Crawford was forty-seven at the time of the operation, and died on the 30th of March, 1841, aged seventy-eight years. It was not until seven years afterward, and when he had twice repeated the operation, that McDowell published any account of it. In 1861 he prepared a brief account of his first three cases, a copy of which he forwarded to his old preceptor, John Bell, who was then travelling on the Continent for his health, and had left his professional correspondence in charge of Mr. John Lizars. The communication failed to reach Mr. Bell, and another copy was forwarded by McDowell

[1] In Gaillard's Medical Journal.

to Philadelphia for publication. The report appeared in the *Eclectic Repertory and Analytical Review* for October, 1816. It reads as follows:

"In December, 1809, I was called to see a Mrs. Crawford, who had for several months thought herself pregnant. She was affected with pain similar to labor-pains, for which she could find no relief. So strong was the presumption of her being in the last stage of pregnancy, that two physicians who were consulted in her case requested my aid in delivering her. The abdomen was considerably enlarged, and had the appearance of pregnancy, though the inclination of the tumor was to one side, admitting of an easy removal to the other. Upon examination, *per vaginam*, I found nothing in the uterus which induced the conclusion that it must be an enlarged ovarium. Having never seen so large a substance extracted, nor heard of an attempt or success attending any operation such as this required, I gave to the unhappy woman information of her dangerous situation. She appeared willing to undergo the experiment, which I promised to perform, if she would come to Danville (the town where I lived), a distance of sixty miles from her place of residence. This appeared almost impracticable by any, though the most favorable, conveyance, though she performed the journey in a few days on horseback. With the assistance of my nephew and colleague, James McDowell, M.D., I commenced the operation, which was concluded as follows: Having placed her on a table of the ordinary height, on her back, and removed all her dressing which might in any way impede the operation, I made an incision about three inches long, from the musculus rectus abdominis, on the left side, continuing the same nine inches in length, parallel with the fibers of the above-named muscle, extending into the cavity of the abdomen, the parietes of which were a good deal contused, which we ascribed to the resting of the tumor on the horn of the saddle during the journey. The tumor then appeared full in view, but was so large that we could not take it away entire. We put a strong ligature around the Fallopian tube near to the uterus; we then cut open the tumor, which was the ovarium and the fimbriated part of the Fallopian tube very much enlarged. We took out fifteen pounds of a dirty, gelatinous-looking substance; after which we cut through the Fallopian tube and extracted the sac, which weighed seven pounds and a half. As soon as the external opening was made, the intestines rushed out upon the table, and so completely was the abdomen filled with the tumor that they could not be replaced during the operation, which was terminated in about twenty-five minutes. We then turned her upon her left side, so as to permit the blood to escape, after which we closed the external opening with the interrupted suture, leaving out at the lower end of the incision the ligature which surrounded the Fallopian tube. Between every two stitches we put a strip of adhesive plaster, which, by keeping the parts in contact, hastened the healing of the incision. We then applied the usual dressing, put her to bed, and prescribed a strict observance of the antiphlogistic regimen. In five days I visited her, and much to my astonishment found her engaged in making up her bed. I gave her particular caution for the future, and in twenty-five days she returned home, as she came, in good health, which she continues to enjoy."

Two additional cases completed this report, all three patients making complete and prompt recovery.

Three years later (October, 1819) McDowell reported in the same journal two additional cases. It will be observed that seven years elapsed from the time he first operated until he made his publication, when he was enabled to add two more successful cases. That so long a time should have been allowed to elapse was most probably due to the surgeon's natural aversion to writing. He was fond of the active duties of his profession and possessed a natural antipathy for literary work. Such men we all know nowadays in the profession, and we must remember that the telegraph, medical societies, and weekly medical journals were not at his command. The communication announcing the successful undertaking covered less than three octavo pages of printed matter, and bore the evidence of careless composition, but all the essential points were given succinctly. If such operations had been performed in our day the most minute circumstances would have been described in detail. McDowell lacked that grace of diction and power of description necessary for such work. Dr. Gross says that writing was a great bore to him, and that he was almost a stranger to the pen and never had any fancy for its use. Perhaps the manner in which this report was made did much to provoke the criticism with which it was received. Dr. James Johnson, the very learned editor of the London *Medico-Chirurgical Review*, was especially severe and satirical in his criticisms. In 1827, when McDowell's work was confirmed by other persons and by additional cases, Dr. Johnson said: "There were circumstances in the narrative of some of the first cases that raised misgivings in our minds, for which uncharitableness we ask pardon of God and of Dr. Ephraim McDowell, of Danville."

Just here it will be interesting to note some points in McDowell's operative technique. The operation, of course, was executed without an anesthetic. The incision was made to the left of the median line, about three inches external to the rectus muscle, and was nine inches in length. After opening the peritoneum he first tied the pedicle with a strong ligature, and then cut open the tumor and removed its contents. He then divided the pedicle, it having been previously tied, and removed the sac. As soon as the incision was made into the abdomen, he states, the intestines rushed out upon the table, and were not replaced until the operation was completed, which, he adds, "occupied twenty-five minutes." He then turned the patient upon the left side to allow all fluids to escape. He closed the incision with interrupted sutures and brought out the ligature attached to the pedicle at the lower angle of the incision. In reporting his cases he omits mention of the material composing the ligature, and I have been informed by a personal friend of McDowell's, now dead, who was a great deal about McDowell's office in his boyhood, that the ligatures used were made of shoemaker's thread and waxed thoroughly before being used. Adhesive strips and a bandage completed the dressing, and, in the author's language, he prescribed "a strict observation of the antiphlogistic regimen."

The special features of the technique are: (1) The incision was made through the muscular layer of the abdominal wall three inches external to the rectus muscle; (2) the cyst was not evacuated until after the pedicle was tied; (3) an effort was made to cleanse the peritoneum of fluids; (4) drainage was sought, as well as escape of ligatures, by bringing the ligatures out at the lower angle of the incision; (5) the operation occupied only twenty-five minutes, expedition being more the result, doubtless, of the want of an anesthetic than

otherwise. In his report of his second case he uses this language: "I laid her side open." In his third case, however, he adopted the median incision, saying in his report of this case, "I changed my place of opening to the linea alba." In all of his cases he ligated the pedicle before separating adhesions or tapping the tumor. In his third case he mentions that the ligatures could not be released for five weeks, at the end of which time the cord was taken away.

In his second report, in 1819, in which he relates two additional cases, he incidentally alluded to his critics and their criticisms in these words:

"I thought my statement sufficiently explicit to warrant any surgeon's performing the operation when necessary without hazarding the odium of making an experiment, and I think my description of the mode of operating, and of the anatomy of the parts concerned, clear enough to enable any good anatomist, possessing the judgment requisite for a surgeon, to operate with safety. I hope no operator of any other description may ever attempt it. It is my most ardent wish that this operation may remain to the mechanical surgeon forever incomprehensible."

If we knew nothing else of McDowell's mental cast and surgical ability these lines would stamp him as a surgeon of broad and elevated views, with a high conception of the science and art of surgery, a keen appreciation of its progressive spirit, and that he knew of the advanced ground upon which he trod.

How many times during his career he performed ovariotomy is not now certainly known. Dr. Jackson states that in 1822 he made a long horseback journey of some hundreds of miles into middle Tennessee, and performed ovariotomy with success upon Mrs. Overton, who resided near the Hermitage, the residence of President Jackson. The only assistants he had in the operation, Dr. Jackson states, were General Jackson and a Mrs. Priestly. General Jackson seems to have been greatly pleased with McDowell, and had him go to his house for entertainment. His nephew, Dr. William A. McDowell, who for five years was his pupil and for two years his partner, tells us that up to 1820 his uncle had done seven ovariotomies, six of which he witnessed, and that six of the seven were successful. Dr. Alban G. Smith succeeded Dr. William A. McDowell as partner of Dr. Ephraim McDowell, and while with him Dr. Smith himself twice performed ovariotomy. The younger McDowell stated later that he knew of his uncle having during his career operated thirteen times, exclusive of the two cases Dr. Smith operated upon; of the thirteen, eight recovered.

McDowell first operated in 1809; in July, 1821, Dr. Nathan Smith, Professor of Surgery in Yale College, performed ovariotomy at Norwich, Conn. Dr. Smith had never heard of McDowell's work and operated in an entirely original way. The incision was made in the median line, and was three inches in length. Dr. Smith states that he waited until the blood ceased flowing before he opened the peritoneum. The omentum being adherent, he tied it away with ligatures made from a kid glove. The pedicle was also tied with the same material, the ligature cut short, the pedicle dropped, and the incision closed. The patient made an uninterrupted recovery. Dr. Alban G. Smith, previously mentioned, reported his first operation, of date of May 23, 1823, in the *North American Medical and Surgical Journal* for January, 1826. He states that he administered a decoction of senna to the patient the night after the operation, producing free catharsis the next day and the day following. Peaslee alludes to this to illustrate the crude methods of the early ovariotomist, while we of the present day recognize Dr. Smith as having been in advance of his times. In 1829 Rogers, of New York, operated successfully, adopting the method of treating the pedicle which Nathan Smith had practised. Bellinger, of Charleston, S. C., operated successfully in 1835, tying the pedicle after Nathan Smith's method. McDowell died in 1830, and from 1835 until 1843 there were absolutely no cases of ovariotomy in this country, according to the searching records of Peaslee and others. In 1843 the late Dr. John L. Atlee, of Lancaster, Pa., and Dr. Alexander Dunlap, of Springfield, Ohio, began their work, joined by Dr. Washington L. Atlee, of Philadelphia, the following year, thus reviving the operation in America. Of these great pioneers in abdominal surgery Alexander Dunlap still survives.

There would be comparatively little credit due McDowell had he without just conception of the nature and character of the undertaking, its difficulties and its dangers, cut into an ovarian tumor, thinking it, perhaps, an abscess or serous accumulation; but educated as he was in the most famous and advanced medical school in the world, experienced in all branches of operative surgery, he had a thorough conception of the nature of the tumor, and deliberately conceived and successfully executed a complete operative procedure previously unattempted in the civilized world. In Great Britain Dr. Robert Houston had, in 1701, laid open an ovarian tumor and evacuated its contents, but he made no attempt to remove the sac. A similar operation had been done by L'Aumonier, but the failure of these eminent surgeons would tend to deter one from rather than to encourage the undertaking. When we think of one living on the border of Western civilization, in a little town of five hundred inhabitants; far removed from the opportunity of consultation with anyone whose opinion might be of value, and nearly a thousand miles from the nearest hospital or dissecting-room; performing a new and untried operation of such magnitude upon the living; before the days of anesthesia; with a full sense of the responsibility and danger; without skilled assistants—our admiration for McDowell's courage and skill rises to its full height, and we feel that he was indeed a man of original ability, clear head, skilled hand, and stout heart.

Dr. Jackson, who conversed with many reliable persons personally acquainted with McDowell, gives this description of his personality: "Dr. McDowell, in person, was nearly six feet in height, of commanding carriage, of a rather florid complexion, with black eyes and dark hair, and deemed in youth quite handsome. He was always remarkable for his strength and agility, and while at Edinburgh was pronounced the swiftest footracer of the whole University. He was one of the kindest-hearted and most amiable of men, overflowing with cheerfulness and good humor, and readily approachable. He seemed to be totally devoid of all reserve and austerity, a tinge of which is generally characteristic of the scholar and professional man, and never appeared

to assume that there was any difference between the plane of his vocation and that of the humblest unlettered artisan.

"He possessed an excellent medical library for his day and locality, and was in the habit of purchasing most of the principal new works on medicine. While having a fair knowledge of the classics, yet most of his professional leisure he gave to history and belles-lettres. Burns was an especial favorite with him, and from his familiarity with the Scottish dialect, acquired while in Edinburgh, his readings and quotations were given with the idiom as perfect as if he had been a native of Auld Reekie.

"As a citizen he was charitable and public-spirited, favoring and contributing, by his means, to most of the enterprises which promised good to the community in which he resided. He was an especial friend to the Center College of Kentucky, coöperating largely by his influence and money toward its foundation, and was, indeed, one of its original corporators and curators. This, too, although its government was by the Presbyterian Church, while he himself was in religion an Episcopalian. The site of the present Episcopalian edifice in Danville, Trinity Church, was a contribution from Dr. McDowell."

All who knew him were impressed with the elegance of his personal appearance, especially with the neatness of his dress and his personal cleanliness.

At the age of thirty-one Dr. McDowell married Sarah, the daughter of Kentucky's famous "war governor," Isaac Shelby, with whom he lived happily and raised a family of six children, two sons and four daughters, only three of whom survive him. Mrs. McDowell was his survivor by ten years. In the later years of his life he removed from the village to a country home, where he spent the later years of his life, still continuing his professional work. He died on the 20th day of June, 1830, after a brief illness.

In affairs relating to human progress and discoveries history repeats itself. The discovery of the circulation of the blood, one of the most brilliant achievements of the seventeenth century, it is said was not accepted by a single one of Harvey's contemporaries over forty years of age. Many years elapsed before the efficacy of vaccination was fully accepted after Jenner's demonstration of its protective power. All great discoveries in science have been destined to be received with doubt, prejudice, and opposition. It was not allowed to McDowell to see the fruits of his immortal work beyond the limits of his own country. As I have stated, Prof. Nathan Smith, the second ovariotomist, had never heard of McDowell's successful work when he undertook the solution of the same problem. When McDowell died, his operation could scarcely be said to have gained a foothold, and after his death it was abandoned until the Atlees and Dunlap revived the operation. In England, Charles Clay did his first operation in 1842. Mr. Spencer Wells began to operate in 1858. The growth and development of the operation up to the present time, when it has become the most successful major operation known to surgery, are familiar to all. That the work of McDowell, published to the world in 1816, opened the way and established the feasibility and practicability of the operation no one pretends to deny. One remarkable circumstance connected with the operation is that it originated and was most practised in the country, while the eminent teachers of surgery in the great cities as a rule refused to accept it and positively opposed it long after it was established in practice. At so late a period as when Dr. Washington L. Atlee lived and practised in Philadelphia, he was refused professional recognition by many eminent surgeons of that city, and was often denounced as a murderer. Another circumstance connected with the birth and growth of ovariotomy, which cannot but impress the student of its history, is that this branch of surgery has been advanced by the labors of a few men. The fate of this operation was for a long time centered in the personality of a few courageous individuals. The high position it has attained is due to the fact that its recorded results are made by a comparatively few operators.

It is beyond the scope of this address to discuss the brilliant achievements of modern surgery in extending the field of abdominal and pelvic surgery. Every important organ within the abdomen has been brought within the surgeon's province until this department of surgery has become the crowning glory of our art. The foundation and history began with ovariotomy; ovariotomy began with McDowell. Careful reflection upon the operative methods of the "Father of Ovariotomy," as I have endeavored to portray them by quoting from his own description, will demonstrate that, except as to asepsis, but little improvement has been made over his methods as originally conceived and carried out. The introduction of the clamp, as practised so long by Sir Spencer Wells, we now know to have been a backward step, which for many years delayed the progress of ovariotomy and prevented an extension of the field of abdominal surgery. With a return to the dropped pedicle as ligated by McDowell, with the simple modification of ligatures cut short, the operation at once under antiseptic precautions reached its present position.

CLINICAL MEMORANDUM.

THE ADMINISTRATION OF A GLYCERIN SOLUTION OF MERCURIC CHLORID AS A PROPHYLACTIC MEASURE AGAINST DIPHTHERIA.

BY WILLIAM C. DABNEY, M.D.,
PROFESSOR OF MEDICINE, UNIVERSITY OF VIRGINIA.

IT seems to be a generally accepted opinion now that the Krebs-Löffler bacilli attack the pharynx, as a rule, first, and that the constitutional symptoms of diphtheria result from the absorption of toxins generated by these germs. If this view be correct, it is evident that the destruction of the pathogenic germs in the pharynx before they have time to generate toxic substances will materially assist in preventing an attack in the case of children who are exposed to the disease. Various methods of applying germicidal agents to the pharynx have been proposed, but the one which I am in the habit of using does not seem to have been employed as yet, so far as I can learn, and it is, I think, well worthy of a trial, because of its simplicity and the facility with which it can be employed.

It consists in administering to the persons who have

been exposed a solution of mercuric chlorid in glycerin. The corrosive sublimate is, of course, the germicidal agent; the glycerin is used as a vehicle because it sticks to the throat, and thus keeps the germicide in contact with the mucous membrane.

I usually give from $\frac{1}{96}$ to $\frac{1}{60}$ of a grain of the bichlorid in a teaspoonful of glycerin every three hours. I direct that the child shall not be allowed to swallow anything else for at least half an hour afterward.

No water is added to the glycerin solution of mercury.

For some time I was in the habit of adding muriated tincture of iron to the mercury and glycerin, but when this is done it necessitates the dilution of the mixture with water, and the *local* action of the drugs is, of course, diminished, so that when used as a *prophylactic* measure I have recently omitted the iron.

In cases of developed diphtheria I have for years used a spray of hydrogen dioxid—one part to four of water—and followed this by the administration of a solution of mercuric chlorid and muriated tincture of iron in glycerin. Perhaps it would be better to give the bichlorid and iron separately, because the former could be given in glycerin without the addition of water, and would thus be kept longer in contact with the pharyngeal mucous membrane.

TERATOLOGIC NOTE.

TWO RECENT ADDITIONS TO THE TERATOLOGIC COLLECTION IN THE WISTAR AND HORNER MUSEUM OF THE UNIVERSITY OF PENNSYLVANIA: SPECIMENS OF ACEPHALUS AND OF MICROMELUS.

BY BARTON COOKE HIRST, M.D.,
PROFESSOR OF OBSTETRICS, UNIVERSITY OF PENNSYLVANIA.

THERE is in the Wistar and Horner Medical Museum of the University of Pennsylvania the best teratologic collection in America. It has grown rapidly of late by gifts from different parts of the United States and from points as distant as the West Indies. If members of the profession continue to contribute as generously as they have, we shall soon have one of the finest collections in the world. A single specimen in the possession of an individual is of little value; but added to a large collection it is itself increased in value, while it enhances the value of the whole collection.

Acephalus. This specimen, kindly presented to me by Dr. Ingalls, of Hartford, Conn., is an example of the commonest form of acardiac acephali. The lower trunk and limbs are comparatively well developed. The thorax, upper extremities, neck, and head are apparently wanting, but rudiments of all these parts may usually be found by a careful dissection. It is very exceptional to find, as in this case, a well-developed hand attached to the upper portion of the trunk without any other part, to all external appearances, of an upper extremity. It is much more common to find an arm represented by an ill-developed stump.

In all the museums of London combined there are but ten *acardiaci*. In our collection there are five.

Rachitis congenita micromelica. In Fig. No. 2 is seen

FIG. 1.

Acephalus.

a typical representation of this rare deformity and congenital disease, rare at least in this country. There is

FIG. 2.

Rachitis congenita micromelica.

hydrocephalus; the limbs are short, curved, and thick, but nowhere fractured. The pelvis has the typical rachitic form—prominent promontory, curved sacrum, widely separated iliac spines, and ischial tuberosities, the result here, of course, of a pull upon the pelvic bones by the muscles attached to them. Nothing is known about the etiology of fetal rachitis. No cause at all could be assigned for it in this case. The student interested in the subject is referred to the excellent article by Winkler in the *Archiv für Gynäkologie*, 1871, and to the bibliography in Müller's *Handbuch der Geburtshülfe*, Bd. ii, p. 807.

1821 Spruce Street.

MEDICAL PROGRESS.

The Results and the Treatment of Wounds of the Common Femoral Vein at Poupart's Ligament.—Niebergall (*Deutsche Zeitschrift f. Chirurgie*, B. xxxvii, H. 3, 4, p. 268) has arrived at some interesting conclusions as the result of a careful study of the results and the treatment of injuries of the common femoral vein at Poupart's ligament. He assents to the view that, as a rule, by reason of the presence of valves in the veins, there is no venous circulation in the lower extremity except through the common femoral vein; but he does not consider as justified the inference that sudden occlusion of the femoral vein at Poupart's ligament must, by reason of the resulting stasis, lead to gangrene of the lower extremity, and that in case of injury of the vein in this situation relief is to be afforded by immediate ligation of the artery. It has been shown that after ligation of the femoral vein, but moderate arterial pressure suffices to overcome the action of the valves in the venous anastomoses, and thus establish a collateral circulation. As the pressure necessary to establish the collateral circulation during life depends upon the energy of the current in the artery, the lumen of this vessel is to be left free. The evidences of stasis (cyanosis, edema) that appear after ligation of the femoral vein, without interference with the artery, result from the elevation of the pressure in the venous system to that present in the arterial system, and represent Nature's method and means of adjustment. These threatening manifestations disappear with a readiness corresponding to that with which the collateral circulation is established. In some cases they have persisted for but a few hours. Among twenty-five cases in which ligation of the femoral vein was practised by reason of the accidental or involuntary injury or unavoidable division in connection with the extirpation of neoplasms, gangrene did not follow in any. The circulatory disturbances that follow ligation of the femoral vein for sudden traumatisms differ only in degree from the disturbances that take place after ligation of the vein for injuries in the course of neoplasm-extirpation. Among ten such cases death followed in but one, and in this the fatal result may have been due to other conditions. The simultaneous ligation of the femoral artery and vein for injury of the vein alone, or of both artery and vein in the course of neoplasm-extirpation, or for trauma of the vein alone, or both artery and vein, is attended with an unfavorable (under the conditions first stated gangrene occurred in 62.5 per cent. of the cases, under the conditions second named in 50 per cent.), though not necessarily fatal prognosis. There is, therefore, no indication for primary amputation. The results of the application of the ligature are first to be awaited, and secondary amputation undertaken only when gangrene sets in. The explanation of these unfavorable results is to be found in the ligation of the artery, in consequence of which the force necessary to equalize the pressure in artery and vein is eliminated. An adjuvant to the development of gangrene of the extremity, after ligation of the artery, is to be found in the resulting local anemia, particularly in the peripheral parts, which in turn may lead to anemic necrosis (particularly after antecedent hemorrhage, cardiac weakness, or arterio-sclerosis). An additional cause for gangrene resides in the hemorrhagic infiltration of the tissues and the sheaths of the vessels. As a result of the increased pressure, the entrance of blood into the collateral circulation is obstructed and the venous return is made more difficult; at the same time the living wall takes up fibrin-ferment from the extravasation, thus favoring coagulation of the blood within the vessels. This influence is particularly noticeable in the thin-walled veins, with their slow blood-current, in which extensive thrombosis forms as soon as the opportunity for resorption of the fibrin-ferment arises. The grounds upon which the recommendation for ligation of the femoral artery and vein for injury of the vein was based (control of hemorrhage, regulation of the circulatory conditions) are insufficient, inasmuch as ligation of the artery often fails to control hemorrhage from the vein; besides, the occasion for a regulation of the circulatory conditions disappears when, as usually happens, the vein is simultaneously ligated. In addition, the resistance of the valves in the collateral venous branches is too great to be overcome by the feeble arterial current. While it is possible thus, by permitting the lumen of the femoral artery to remain free, and avoiding infiltration of blood and its consequences, to ligate the femoral vein without danger of gangrene of the extremity, even after antecedent trauma, there remains a group of cases (antecedent hemorrhage, disease of the walls of the artery), providing the condition of the walls of the vein is beyond suspicion, in which partial lateral ligation of the vein would seem preferable; also in case of small wounds of the vein, thus permitting the current of blood through the vessel to be maintained. Under such circumstances compression, antiseptic tamponade, would be applicable under peculiarly favorable conditions, such as a small wound of the vein and soft parts in case of accidental trauma. The possibility of the occurrence of secondary hemorrhage as a result of slipping of the ligature must be borne in mind after lateral ligation. The most secure and most serviceable means of ligature are lateral suture of the vein and the application of forceps for a period of twenty-four hours. The question of total or partial ligature will be decided by the nature of the wound in the vessel, and the character of the injury. Malignant neoplasms, involving the walls of the vein so as to prevent its isolation, indicate resection of the vessel with circular ligature; the same procedure will be required if the injury of the vein involves the greater part of the circumference of the vessel, or if the posterior wall of the vein is also involved. At least two ligatures will be required,

one peripheral, the other central; a third ligature will be required when the mouth of the vena profunda lies between the other two ligatures. The ligatures are to be applied as closely above and below the seat of injury as possible without incurring any risk of their slipping. If the wound in the vein is small, if it elongate longitudinally, and if it involve an otherwise healthy vessel, lateral ligation is indicated. Tamponade may be tried, but is to be discarded if it does not succeed upon the first trial. In case of slight injuries in the course of neoplasm-extirpation, when the conditions are exposed to view, dependence will not be placed upon tamponade. In case of antecedent trauma (puncture), enlargement of the external wound will usually be necessary to determine the nature of the injury. The ligation of the femoral artery for the control of hemorrhage from the femoral vein or from lateral branches of the femoral vein must be considered a mistake under all conditions, and not permissible. If both artery and vein are injured, or if both must be resected in the removal of new-growths, gangrene is to be expected. The operation is to be followed by scrupulous removal of all extravasated blood, and by vertical suspension or elevation of the lower extremity. All recommendations calculated, in view of the supposed dangers of venous stasis, to lower the arterial pressure (immediate compression of the artery after ligation of the vein, ligation of the superficial femoral artery) are to be rejected as contra-indicated and injurious.

Tuberculosis of the Penis.—Malécot (*Annales des Malad. des Organes Génito-urinaires*, 1893, No. 11, p. 838) has reported an instance of tuberculosis of the penis—a rare localization. The case occurred in a boy, fourteen years old, on whom the rite of circumcision had been practised a week after birth, and who for three years had complained of irritability of the bladder. Micturition was frequent and painful, and the urine was often mixed with blood. For about eighteen months there had been both diurnal and nocturnal incontinence of urine. The lad appeared pallid and emaciated, but no pulmonary lesion was detectable. The ulceration involved the extremity of the glans penis, and occupied an area about the size of a silver quarter-dollar, having the meatus urinarius as its center. The borders of the ulcer were a little irregular, but not undermined, and were discolored, presenting here and there slight prominences. The base was pale, smooth, and presented a few vessels about the meatus, which appeared somewhat retracted. Although the ulcer was constantly soiled by urine it presented no drop of pus. It was soft and free from pain, even on pressure, and there was no involvement of the inguinal glands. Direct examination of scrapings from the surface of the ulcer failed to disclose the presence of tubercle-bacilli, but inoculation-experiments demonstrated the correctness of the clinical diagnosis of tuberculous ulceration.

Akromegaly in Father and Son.—Bonardi (*Arch. Ital. di Clin. Med., 1893; Rev. des Sci. Méd.*, No. 85) has recorded the case of a man, seventy-four years old, whose father had been affected with akromegaly, and who for a long time presented increased size of the head, elongation of the face, enlargement of the tongue, hypertrophy of the hands and feet, and dorsal kyphosis. After death a tumor of the pituitary body was found, in conjunction with generalized endartertis and sclerotic atrophy of the thyroid gland.

THERAPEUTIC NOTES.

Potassium Permanganate as an Antidote to Opium and its Alkaloids.—It is related that a physician of New York recently demonstrated, in the presence of a number of colleagues, in his own person the efficacy of potassium permanganate as an antidote to morphin. He is said to have swallowed three grains of morphin sulfate in solution, and immediately afterward four grains of potassium permanganate dissolved in four ounces of water, without the development of the usual effects of morphin. It is maintained that morphin, or any of the salts of opium, is immediately rendered inert by contact with potassium permanganate, the one drug seeming to have a special affinity for the other, the one being a reducing agent, the other an oxidizing agent. As the antidotal action is chemic rather than physiologic, it is essential that the permanganate be administered soon after the ingestion of the opiate. It was first believed that the permanganate is without influence after the opiate has been absorbed, but experiments upon animals seem to indicate that if the former is introduced into the veins at not too great an interval after the ingestion or injection of the latter an antidotal influence is also exercised.

Internal Remedies for Vesicular Eczema.—Phillips (*British Medical Journal*, No. 1726, p. 175) details the results of a study of the effects obtained from the internal administration of various remedies in the treatment of vesicular eczema. Calcium sulfid was used in a large number of cases, but with disappointing results. Ichthyol, in pill-form, seemed to have a slight modifying influence in some cases; in one case of relapsing vesicular eczema of the arms and hands the patient believed that the drug was of more benefit than any previously used remedy. Calcium chlorid was used in a large number of cases, but with entirely negative results. Antimonium and potassium tartrate, in doses of from one-tenth to one-sixth of a grain thrice daily, continued for long periods, seemed to be helpful in a small proportion of cases. The results from thyroid feeding were negative. The hypophosfites appeared to be occasionally useful.

Thyroid Extract in the Treatment of Syphilitic Psoriasis.—Gordon (*British Medical Journal*, No. 1726, p. 186), has reported the case of a woman, forty-nine years old, who presented palmar and plantar psoriasis, together with other manifestations of syphilis, in the course of which potassic iodid, and arsenic and chrysophanic acid had been employed, with but little improvement. It was resolved to give thyroid extract a trial. All treatment was withheld for a week. At the end of this time 20 minims of a glycerin extract of thyroid gland were prescribed daily. Marked improvement shortly set in, which proved persistent. Subsequently, treatment with iodid was resumed.

ENGLISH AND GERMAN VIEWS OF GOUT.

ANYONE who has read the careful collective review of the newer literature on gout by PROF. C. VON NOORDEN, which recently appeared in the *Berliner klinische Wochenschrift*,[1] will have been struck by the comparison of the work done in England with that coming from Germany. The English, with an abundance of clinical material, have given us by far the best account of the symptomatology and general course of the disease, while the Germans, with their tendency for research and their excellent laboratory equipment, have contributed to the chemic rather than to the clinical side of the process—a side which has in England, if we except the work of one or two men, remained in the condition in which it was left fifty years ago.

SIR DYCE DUCKWORTH in a comprehensive work[2] has included, along with his own observations, the views of his fellow-countrymen upon the variations in the clinical picture which the disease may present, and has outlined the treatment clearly and with calm judgment. In his comments on the pathogenesis and theory as to the essential nature of the disease, however, we find little else than hypotheses built upon the chemistry of GARROD. He has referred, it is true, to the work of HAIG, the main points of which have been embodied in a book written by the latter entitled *Uric Acid*.[1] According to HAIG there is no increased formation of uric acid in gout, but the blood being less alkaline than normal is unable to hold uric acid (or its salts) in solution. The kidneys cannot remove these constituents sufficiently rapidly when the alkalinity of the blood is lowered, and they are consequently deposited in the tissues and joints, where the lymph-stream is slow and of low alkalinity. It will be noted that HAIG'S theory agrees with GARROD'S in so far as it regards gout as dependent essentially upon an excess of uric acid and its salts within the body; the distinction between the two is simply that GARROD attributed the accumulation to renal insufficiency, while HAIG lays the fault to an alteration in the composition of the blood. The idea so often met with in English literature, that acute articular rheumatism and gout are only different manifestations of one and the same disease, is no less astonishing to the German than it is to the American mind.

SIR WILLIAM ROBERTS[2] has broken loose from the traditional views, and has set up a new theory based upon personal physiologic and chemic investigations. His ideas have been clearly expressed in the Croonian lectures for 1892, and are already so well known that we shall not enter fully into them here. It will be sufficient to recall the main points: In the healthy body uric acid and neutral and acid urates play no important part in metabolism. It is an easily soluble "quadriurate" that is formed in the tissues, that circulates in the blood, and is excreted by the kidneys. If there be over-production or deficient elimination from any cause, this quadriurate is transformed, through the influence of the alkali of the blood, into the difficultly soluble "biurate." This latter, existing at first in a gelatinous form, is easily changed into a less soluble anhydrid, to be finally deposited in crystalline form in certain parts of the body, where the temperature is low (*e. g.*, in the peripheral joints), and particularly where the lymph contains a relatively high

percentage of sodium chlorid (*e. g.*, synovial fluid). These salts when once deposited can only with great difficulty be redissolved.

An attempt has been made in a recent valuable monograph by LEVISON[1] to explain all the known facts of gout by means of the "quadriurate" theory, HARBACZEWSKI'S doctrine, that the uric acid originates from nuclein, completely independently of the formation of urea in the body, being accepted at the same time in its entirety. LEVISON comes back, however, in concluding, to the older idea of GARROD, that gout depends on a retention of uric acid as a result of renal insufficieny, and points out that heredity, immoderate alcoholic indulgence and excesses in nitrogenous food are factors common alike in the etiology of both gout and contracted kidney.

Among the German contributions none has attracted more attention, perhaps, than that of E. PFEIFFER.[2] It may be remembered that PFEIFFER determined that in his patients who suffered from acute attacks of gout, but showed no chronic alterations (*e. g.*, tophi), there was, as a rule, less uric acid excreted than in health, while in patients with chronic changes the amount of uric acid in the urine was normal or a little increased. If the uratic deposits in the tissues in the latter case be considered, the total formation of uric acid is found to be abnormally great. In both classes of cases the amount of urea excreted daily is below the normal, and PFEIFFER lays stress on his view that in the gouty patient, even before any permanent alteration has taken place in the tissues, a perversion of the total metabolism can be demonstrated. More numerous and more extensive investigations of the total metabolism, as VON NOORDEN points out, must be made before such conclusions can be regarded as safe.

It has further been shown by PFEIFFER, that by passing 100 c.cm. of the day's urine through a filter charged with from 0.2 to 0.5 gr. of pure uric acid, there is less uric acid (precipitable by hydrochloric acid) in the filtrate than in the unfiltered urine. The difference is represented by what he calls "easily separable" or "free" uric acid (*leicht ausscheidbare oder freie Harnsäure*). Applying this test to gouty urine he found (1) that during and just after an acute attack there is none or almost none of this "easily separable" uric acid present, and (2) that in the intervals between the attacks and in chronic gout, nearly all of the uric acid of the urine (precipitable by HCl) is of this "easily separable" variety. It is to be noted that healthy urine loses by filtration through 0.2 gr. of uric acid rarely more than 35 per cent. of the amount which can be precipitated by hydrochloric acid.

No sooner a new fact than a new theory, and PFEIFFER assumes that the blood, like the urine, in gout, holds its uric acid in "more easily separable" combinations than in health, and thus the deposits in the tissues are easily to be accounted for. The acute attacks result from the local irritating effects of a sudden solution of the tissue-deposits, consequent on an increase in the alkalinity of the blood or lymph; "firmer" (*gebundenen*) combinations of uric acid then circulate in the blood and are given off in the urine.

These observations have been confirmed by CAMERER, SCHETELIG, and MORDHORST; and LEUBE has gone so far as to state in his text-book that they are of great importance for diagnostic purposes, even though the cause of this peculiar behavior of the uric acid in gouty urine is as yet not clear. Were these phemonena constant for gout, and did they never occur in other diseases, a diagnostic gain would certainly have to be admitted, for it is exactly in the intervals between the attacks that the diagnosis is most difficult, and here, according to PFEIFFER, the urine is most abnormal. But FELIZIANI, as well as ROBERTS, contradicts these statements of PFEIFFER, and more, even should his findings in gouty urine prove to be correct, the signs are by no means pathognomonic, for VON NOORDEN has demonstrated a wholly analogous behavior of the uric acid in certain febrile disturbances and in various affections of the lungs, heart, and stomach. Both the theoretic and practical interest of the observations will of course be materially diminished if VON NOORDEN'S results are confirmed.

EBSTEIN'S[1] theory of a local accumulation of uric acid, which leads first to inflammation and necrosis of tissue, and later to deposition of urates in the diseased part, has been modified by VON NOORDEN.[2] The latter does not believe that the primary changes in the tissues result from the action of uric acid, but prefers to assume that the formation and de-

position of the uric acid are the results of a secondary process set up by the presence of a special ferment acting locally, entirely independent of the amount and behavior of the uric acid formed elsewhere in the body.

Nearly all of the recent articles on gout have had something to say regarding the treatment. As to the most suitable dietary there is marked disagreement; Roberts, Haig, and Duckworth urge the advantages of a vegetable diet, while Pfeiffer and von Mering agree with Cantani in allowing a liberal supply of meat and limiting the carbohydrates. It has seemed to us that, in the existence of such contradictory opinions, it may be that the quantity of the food ingested, rather than the quality, is of importance for the well-being of the patient. Badt and Levison, in curious consonance with the old saying, *Quod ali cibus est aliis fuat acre venenum*, suggest that the diet be ordered, not from the diagnosis of gout, but according to the "individuality of the patient." Still it has been admitted by all authors from very early in its history that gout is most common in countries where "meat-eating" habits prevail.

The therapeutic value of the alkaline treatment has been, it would appear, much overestimated, at any rate as far as the good derived from the alkalies in themselves is concerned. Roberts, especially, insists that the benefits of the method are due entirely to the large amounts of water taken. The alkalies are nevertheless much in vogue, and will probably continue to be used, for people are often ready to "take medicine" when they cannot be induced to "drink water," and, besides, the swallowing of large quantities of plain water (to which neither acid nor alkali has been added) is by no means easy, as anyone may readily convince himself who will make the attempt on several successive days.

Mordhorst[1] has strongly recommended the use of the "Wiesbadener Gichtwasser," which contains tolerably large amounts of bicarbonate of soda. When drunk for some time, it renders the urine of both the day and the night slightly alkaline. Occasion is taken by von Noorden in this connection to correct a statement of wide currency, viz., "that since uric acid and urates separate out only in an acid medium, it is necessary that the body-juices in the neighborhood of gouty deposits should be acid." While it is certainly true that the crystals in the deposits are generally those of acid urates, it is not true that the surrounding fluids are necessarily acid, and indeed in three cases in which fresh, soft tophi were opened and the reaction of the contents tested they were found to be alkaline, although acid urate crystals were present in large numbers.

That these acid salts should be stable in an alkaline medium seems at first paradoxic, but the following experiment sheds some light on the subject. A uric acid concretion, sterilized and dried *in vacuo* over sulphuric acid, was suspended in sterile blood-serum for twenty-four hours. Only after the addition of relatively large amounts of alkali could any appreciable loss in weight in the mass be detected. On the other hand, an aqueous solution of alkali of the same strength, under similar conditions, soon dissolved an essential part of the concretion. We learn from this that the alkali in the blood behaves very differently from alkali in water—in the former the affinity for acids is as it were held in bond. We already know something of a similar behavior of acids in albuminous fluids, and ignorance concerning the "bound" and "free" hydrochloric acid of the gastric juice has been largely responsible for the extensive polemic literature on the relative value of the various tests for hydrochloric acid.

Equally interesting is an experiment of Mendelsohn's[1] through which it was shown that a mixture of a strongly alkaline water (Vals), with an equal volume of distilled water, dissolved twice as much of a given weight of uric acid as did equal parts of the same alkaline water and urine, the urine (like the blood-serum in von Noorden's experiment) depriving the other constituents of the power of dissolving uric acid. The relation of experiments such as these to the question of the therapeutic value of the alkalies becomes at once apparent.

It would be interesting, had we the space, to refer to the various researches undertaken to determine the action of *piperazin* in the body, and its value as a remedy for gout. As everyone knows, this substance has a strongly alkaline reaction, and an extraordinary power in solution of dissolving uric acid. These chemic properties gave rise to hopes which have not been realized, as far as any marked increase in the elimination of uric acid after its

[1] Mordhorst: "Zur Lehre von der Gicht," Wien. med. Woch., 1893, No. 10-16. Also, Verh. des X. Congr. f. in. Med., 1891, S. 443, and Therap. Monatsh., 1893, No. 8.

[1] Mendelsohn: "Zur Therapie der harnsäuren Diathese," Verh. des XII. Congr. f. in. Med., 1893, S. 367.

administration is concerned, and confidence in its powers as a uric-acid solvent has been much shaken since MENDELSOHN has shown that it (like the ordinary alkalies) when added to normal urine does not increase the power of that fluid to dissolve uric acid.

To discuss this side of the subject fully would carry us too far, but we cannot close this article without first referring, if only briefly, to the highly interesting investigations made by MEISELS,[1] and independently by BIESENTHAL,[2] concerning the action of piperazin upon the uric acid in living birds. These workers produced the well-known experimental nephritis in hens and pigeons which results from subcutaneous injection of potassium chromate and leads to a retention in the blood of the urinary constitutents. It will be recalled that the end-product of proteid metabolism in birds is not urea but uric acid. Ordinarily in such cases of artificially induced uremia, crystalline urates are deposited in different parts of the body, but when the birds were treated with piperazin the deposits could in the majority of cases be prevented. In the few cases in which deposits occurred in spite of treatment it is fair to presume that the retained uric acid and the absorbed piperazin did not exist together in the blood in the most suitable proportions. The administration of alkalies had no power to prevent the deposits. The piperazin, like urocedin (which has been shown by MENDELSOHN to prevent the separation of urates in the urine from solution), could not dissolve the deposits when once they had been laid down.

While we welcome as extremely suggestive the results of these experiments of MEISELS and BIESENTHAL, yet we agree with VON NOORDEN in advising great caution as regards their application to gout in human beings. As he says, the birds are not *gouty*, but simply *uremic*, and, moreover, it is very probable that the relations of the blood and lymph to uric acid in birds are quite different from those in mammals. One difference between the uric-acid retention of gout and that produced artificially in birds has already been demonstrated: in the latter the precipitation occurs on the free surface of endothelial structures, apparently on account of the concentration of the lymph, while in the former the uric acid is to be found within the bodies of the cells and in the intercellular substance, a deposition of urates occurring on the free surface of a lymph-sac (joint-cavity) only after erosion of the cartilages.

The treatment of gout by piperazin must for the present, then, be looked upon as purely empiric; the belief that we have a rational therapeutic basis in the limited knowledge thus far gained from animal experiments would only lead us in false directions and prevent further progress. The drug appears to be favorably viewed by many, and recently WITTZACK,[1] especially, has warmly supported the earlier recommendations of BIESENTHAL as to its value.

From what has been said it is clear that the problems of gout require for their solution long and patient chemic research and a much more intimate knowledge than we have at present of the complex phenomena of animal chemistry. When what occurs normally is so imperfectly understood, it is but little wonder that the still more subtle changes which occur under pathologic conditions, deep down in the body-metabolism, should prove so elusive when we attempt to grasp them. But the corps of trained and earnest workers in this field is rapidly swelling its numbers, and it is not too much to hope that when the new science of "Physical Chemistry," in which such enormous advances have been made during the past eight or nine years (through the efforts of VAN 'T HOFF, ARRHENIUS, OSTWALD and others), shall have been applied to the problems of physiology and pathology, many of the things now secret will be revealed.

EDITORIAL COMMENTS.

Transient Aphasia in the Course of Pneumonia.—It is not uncommon to encounter palsy, and at times other evidences of interference with cerebral function, of varying degree of transiency, in persons who exhibit manifest or probable arterio-sclerotic changes. The explanation ordinarily given is that of ischemia and interference with the nutrition of the brain, resulting from narrowing of the lumen of the cerebral vessels, in consequence of the thickening of their walls as a result of the degenerative process. Similar phenomena are also not infrequently observed in cases of acute or chronic nephritis, and here the explanation is a somewhat different one. It may be conceived, on the one hand, that a dropsical effusion has taken place and

[1] Wittzack: "Harnsäure-Diathese und Piperazin," Münch. med. Wochenschr., 1893, No. 28.

exerts compression of the brain; or, on the other hand, that there are present in the blood noxious products that the kidneys have failed to remove. Manifestations of a like character are from time to time further observed in the course of the infectious diseases. In some of these cases structural changes are induced, but there are others from which, on account of the transiency of the symptoms and the absence of sequelæ, the occurrence of a gross lesion can be excluded. In a communication presented at a recent meeting of the Société Médicale des Hôpitaux, CHANTEMESSE (*La Semaine Médicale*, 1893, No. 73, p. 582) called attention to the occurrence of transitory aphasia in the course of pneumonia, and cited an illustrative case. It was pointed out that when this complication occurs it usually appears toward the close of the second or third day of the attack, being ordinarily preceded by headache and vertigo, and sometimes by numbness and tingling in the right side of the face and in the right upper extremity. The aphasia may set in abruptly, without loss of consciousness; at other times it may become manifest after a typical apoplectiform seizure. The characters of the impairment of speech do not differ from those dependent upon an organic lesion of the third frontal convolution upon the left side of the brain. The paralysis may involve the entire right side of the body, but usually only the inferior portion of the right side of the face, the right half of the tongue, and the right superior extremity are affected, while, as a rule, sensibility and the reflexes are not altered. In pronounced cases the paralyzed parts may be the seat of increased redness, and edema more or less circumscribed and increased by heat. These phenomena persist commonly for from a few hours to a few days, and seem in no way to influence the primary disease. Their fugaciousness excludes the possibility of organic disease, and their character and association are unlike those of hysteria. It seems probable that the condition is to be ascribed to the action of the toxic products of the activity of the organisms upon which the pneumonia depends, either directly upon the nervous centers or indirectly through the intermediation of the vasomotor system, causing contraction of the cerebral vessels to such a degree as to compromise the function of the parts controlling the peripheral mechanism. In the cases observed by CHANTEMESSE the pneumonia affected the right side.

Symphysiotomy in America.—DR. ROBT. P. HARRIS read his epoch-making paper on "The Remarkable Results of Antiseptic Symphysiotomy" before the American Gynecological Society at its seventeenth annual meeting held in Brooklyn on September 20, 1892. (See THE MEDICAL NEWS, October 8, 1892, p. 416.) Ten days later DR. CHAS. JEWETT, of Brooklyn, performed what for a long time was believed to be the first symphysiotomy on the American continent. Three days after this Dr. BARTON COOKE HIRST operated successfully in Philadelphia. (See THE MEDICAL NEWS, October 15, 1892, p. 451.) DR. HARRIS, to whom so much credit is due for the revival of the procedure, has by his persistence unearthed the fact that the first operation in America was performed on March 12, 1892, more than six months before his paper was read, and by DR. WM. THOS. COGGIN, then residing in the town of Freedman, Etowah County, Alabama, and now of Athens, Georgia, with a successful result for both parent and child. DR. COGGIN had become familiar with the operation while abroad several years before, and, convinced of its utility and its preference in suitable cases to embryotomy, performed it when the opportunity arose. It transpires that DR. COGGIN was anticipated only a short time, by PROF. PINARD, of Paris, in the performance of the first symphysiotomy outside of Italy. PINARD operated on February 4, 1892, seven weeks before COGGIN, the mother recovering, the child dying. From a paper read by DR. HARRIS at a recent meeting of the Philadelphia Obstetrical Society, we learn that in the year 1892, symphysiotomy was performed throughout the world in 81 accessible cases, with 11 maternal (and 24 fetal) deaths, distributed as follows: France 37 operations, with 6 deaths; Germany 11, with 2 deaths; Austria 6, with 1 death; Italy 9 and the United States 8, with no death; Russia 4, with 1 death; Brazil, Ireland, Switzerland, Holland, Canada and India each 1, with 1 death, in the Holland case. In the first six months of 1893 there were more symphysiotomies than in the whole of 1892, and the record of the year will probably reach two hundred, or more than the number of Cesarean and Porro-Cesarean cases of the world together.

As far as ascertained, there were twenty-seven symphysiotomies in the United States in 1893, and forty operations in North and South America, with four women and nine children lost, a maternal mortality of 10 per cent. There have been twelve operations in Philadelphia, or one-third of those in the United States. The operation has been performed in ten States and by twenty-six operators. Twenty-eight of the cases were in large cities.

Privileged Communications.—It is the object and purpose of the law to enable a patient to make a full statement of his physical infirmities to his physician, with the knowledge, says the Supreme Court of California, in the case of Flint's Estate, that the law recognizes the communications as confidential, and guards against the possibility of his feelings being shocked, or his reputation tarnished by their subsequent disclosure. To him the considerations are even more weighty that the privilege remain inviolate after he has gone to his grave, for his good name is left behind, deprived of his protecting care. His rights are not buried in the grave, and heirs and devisees quarrelling among themselves over a division of his patrimony should, in justice to his memory, not be allowed to waive the privilege. Consequently, the court holds that a statute which provides that, "a licensed physician or surgeon cannot, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient which was necessary to enable him to prescribe or act for the patient," rests upon a sound public policy, and cannot be waived by an heir seeking to set aside a will by proving by an attending physician that he prescribed for the testator for mental trouble. Reference is made to New York State, where there is a similar law, except that it provides that the privilege is present, unless "expressly waived by the patient," and it is uniformly held by the courts that the patient alone can waive the privilege, and when such patient is dead the matter is forever closed.

This would also seem to be the doctrine of many of the other States. But in Michigan, Missouri, and Indiana there are decisions under quite different statutes, which can, perhaps, give an heir power to waive the privilege. And in some other States the legal representative, the administrator, can waive it.

Typhoid Fever without Intestinal Lesions.—If it be shown that the affection most commonly known by the names of typhoid fever and enteric fever may exist in the absence of fever and without the presence of intestinal lesions, it would seem as if some more accurately descriptive name were needed. We have on a previous occasion pointed out the occurrence of apyretic typhoid fever, and evidence is not wanting that typhoid fever may exist without intestinal lesions. Three cases of the kind last mentioned have been reported by KARLINSKI (*Wiener medicin. Wochenschr.*, March 14, 21, 1891), and recently another by DU CAZAL (Soc. Méd. des Hôp., April 7, 1893; *Rev. des Sci. Méd.*, No. 85, p. 172). The last was that of a patient who for three weeks presented the symptoms of classic typhoid fever: headache, epistaxis, meteorism, rose-spots, continued fever, and albuminuria, with the development of bilateral pneumonia on about the fifteenth day. The case terminated fatally and upon post-mortem examination the lungs were found almost completely hepatized and the spleen enlarged, while the intestines and the mesenteric glands were perfectly uninvolved. Bacteriologic examination of the spleen, however, demonstrated the presence of typhoid-bacilli in pure culture. Cases of this kind must be considered as analogous with those of the exanthemata in which the cutaneous eruption is wanting.

Variolin.—It has come to light that in a neighboring city, in which wisely all school-children must be protected by vaccination or a previous attack of smallpox, some of the children have been treated "by the homeopathic administration of variolin in a highly potential state." Is it possible that the public will insist upon the inevitable sacrifice that must occur among those so treated in case of an epidemic of smallpox in order to demonstrate the fallacy and the absurdity of so-called homeopathic principles and practice?

REVIEWS.

SURGERY. By BERN B. GALLAUDET, M.D., Demonstrator of Anatomy and Clinical Lecturer on Surgery, College of Physicians and Surgeons, New York; Visiting Surgeon, Bellevue Hospital, New York; and CHARLES N. DIXON-JONES, M.D., Assistant Surgeon, Out-patient Department Presbyterian Hospital, New York. Being the final volume of the "Students' Quiz Series," edited by BERN B. GALLAUDET, M.D. 12mo, pp. 291, with 149 illustrations. Philadelphia: Lea Brothers & Co., 1893.

THE conviction is expressed by Dr. Gallaudet in the preface to this litfle book, that a "book written not as a compend or digest of surgery, but rather as one which would *explain*, would prove of advantage." As a consequence of this, one is impressed by the difference between the descriptive character of the replies to the questions which are given, and the dogmatic statements usually constituting the substance of books of this class. The idea is undoubtedly a happy one, and the result is that the book is not only readable, but that the facts which it presents to the student are set forth in such a manner as to appeal to his reason as well as to his memory, and, therefore, the more easily and permanently impressed upon him. The danger, so often incurred in "compends," of encouraging the acquisition of a superficial knowledge of the subject is also, as far as possible, avoided.

The style of the book is clear as well as compact. Each subject that it embraces we find fairly dealt with. Among the sections which we would especially commend for clearness and thoroughness are those upon Surgical Bacteriology, Diseases and Injuries of the Brain, and Diseases of, and Operations on, the Abdominal Viscera. The illustrations, of which there is a goodly number, are excellent and well selected, and the tabular presentation of many subjects will enable the student to fix the facts more readily in his mind. We do not notice any important omissions. One or two points which strike us are that, in speaking of elastic compression by the Esmarch strap, in the management of arterial wounds, it would have been well to have said a word of caution against the undesirable results sometimes obtained from its being too long kept upon a limb; and another is, that in mentioning the operations for hemorrhoids nothing is said of the "clamp and cautery" operation, a procedure which has many advocates among practical surgeons.

The book is up to the times, and well fulfils its object. We are sure that it will soon acquire the popularity it deserves.

A MANUAL OF PRACTICAL HYGIENE, DESIGNED FOR SANITARY AND HEALTH OFFICERS, PRACTITIONERS, AND STUDENTS OF MEDICINE. By W. M. L. COPLIN, M.D., Adjunct Professor of Hygiene at Jefferson Medical College, etc., and D. BEVAN, M.D., Instructor in Hygiene at Jefferson Medical College, etc. 8vo, pp. 441, and index. Philadelphia: P. Blakiston, Son & Co., 1893.

SCIENCE is cosmopolitan, and it is, therefore, not wholly commendable that one should note the nationality of a scientific work, but it is a matter of gratification that so useful and creditable a text-book as this is of American authorship. The work has been long in preparation, and a perusal of it shows that the delay has not been due to inaction, but to a desire to collect and properly arrange the vast amount of data of a rapidly growing science. The authors are both practical workers in the bacteriologic laboratory and teachers of hygiene, and are, therefore, enabled to give in concise and correct form the essential features of all microbes now known to be causally connected with diseases in man. Dr. Bevan has skilfully drawn, and the printer has skilfully printed in colors, the actual outlines of the important species. We must note here a commendable detail, namely, that in the chapter on Bacteria the drawings are, with one exception, drawn to a uniform scale of enlargement, which is most useful to students, who always have difficulties in comprehending these minute magnitudes. Equal praise cannot, however, be given to some of the details in the arrangement of the topics in this part. A succession of

Tetanus, Tinea Versicolor, and Tuberculosis suits the index but not the matter of a text-book.

The authors express freely and positively their opinions on disputed questions. It may be a question, however, if they are not too sanguine or too severe in some measures. Thus, we are told that marriage between tuberculous individuals should be prohibited, and association with the non-infected rendered impossible. "Paper," says a German proverb, "is patient," and it is not likely that simple dogmatic statements like these will work any good. Moreover, Cornet, in his elaborate paper, has shown that a great deal may be done toward rendering the tuberculous patient harmless to those around him.

It is gratifying to note that considerable care has been taken with the terminology; chemic terms are given mostly in the approved modern forms. A book like this has a considerable missionary function, and can do a great deal of good in promoting correct phraseology in chemistry and biology, in which medical men are not always exact.

We must note before leaving the matter the extended collection of data on the climate of various parts of the United States. The collection of these data has involved much labor.

The publishers' part has been well done, and we can feel sure that the book will quickly assume an honorable position in the field to which it is dedicated.

A Text-book of Physiological Chemistry. By Olof Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Second Swedish and from the Author's Enlarged and Revised German Edition. By John A. Mandel, Assistant to the Chair of Chemistry in the Bellevue Hospital Medical College, etc. First edition, first thousand. 8vo, pp. x, 486, and index. New York: John Wiley & Sons.

Much valuable matter in applied organic chemistry is presented in Swedish and Dano-Norwegian literature, which finds its way but slowly and imperfectly into English, in consequence of the limited knowledge of the Scandinavian languages possessed by medical men in this country and in England. Hammarsten, Sebelien, and Kjeldahl have been especially noted for their practical researches in physiologic chemistry. The present treatise is, therefore, welcome, and proves to be an excellent summary of important facts of the science. The author's preface to the original Swedish edition is not given, but that to the German edition is, and in it he calls attention to the fact that the work is not intended as a detailed text-book, and that the arrangement of the matter is made necessary by the manner in which the subject is taught in Sweden, as laboratory practice in physiologic and pathologic chemistry is obligatory with medical students. The work is, however, not a manual of laboratory practice alone. Full space is assigned to descriptive matter. The analytic and practical parts are distinguished by special type.

In an introduction covering twelve pages the author discusses the general chemistry and physics of vital processes, and furnishes us with a clear and interesting sketch of the important actions produced by organized and formless ferments, *i. e.*, microbes and enzyms, especially the hydrolytic actions. Reference is also made to the nature of antiseptics, but the statement that salicylic acid does not noticeably interfere with the action of enzyms is not invariably applicable. The subject of the toxic products of putrefaction and physiologic action is also concisely and clearly presented. The chapter on milk is highly commendable, giving all the important and established data about cow's milk, as well as human milk. We note that the theory that the fat-globules are surrounded by an albuminous envelop seems to be untenable.

Over one hundred pages are devoted to the urine, thus enabling the author to give an elaborate account of the normal and abnormal conditions of that secretion. Many tests are given, but the translator recognizes that the chapter is rather too extended for the practical workers, and suggests a reference to smaller manuals for the quick and clinical methods.

The work, taken as a whole, is a valuable addition to the available sources of information for teachers of physiology and medical chemistry. The translation is well done, but the chemic terms are not always satisfactory. Such terms as "cholesterin," "benzol," "glycerin," should be represented by their modern forms, "cholesterol," "benzene," "glycerol."

In typographic execution the book is not especially pleasing. The impression is too heavy, and the practice of printing all proper names in small capitals is not to be commended.

A System of Genito-urinary Diseases, Syphilology, and Dermatology. By Various Authors. Edited by Prince A. Morrow, A.M., M.D., etc. With illustrations. In three volumes. Vol. II: Syphilology. 8vo, pp. 917. New York: D. Appleton & Co., 1893.

Like its predecessor, this large and handsome volume is mainly the work of New York men, fifteen of its twenty-three authors claiming residence in that city.

Not many years ago syphilis was a leading topic in the minds of the profession, but of late it has been largely overshadowed, or rather crowded out, by the great advances made in other directions. It is well, perhaps, that interest should be revived in it; but we do not think that the book before us is an important addition to the literature of the subject, calculated to eclipse by its superior merit the admirable standard works already existing. Of course, there have been within the last two decades, in Europe especially, some valuable records of observation and experiment, which seem to be freely quoted in these pages. But the reader will not, in our opinion, find that much progress has been made in practical every-day matters.

In his preface the editor says: "Modern bacteriological researches have given us a clearer conception of the important rôle played by microörganisms in the production of syphilitic phenomena. While the theory of the bacterial origin of syphilis rests upon hypothesis rather than upon absolute demonstration, yet the general recognition of a specific microbe as the essential etiological factor of the action of its toxins upon the tissues, and of the pathogenetic influence of pyogenic microbes, has thrown a flood of light upon the interpretation of many of the morbid processes of syphilis." We must confess our

inability to understand this glittering generality, and our doubt as to the value of a theory which rests upon an hypothesis. Nor can we find in the body of the work evidence of any such brilliant illumination. Our conviction remains that syphilis is as yet a disease the phenomena of which can be described but not explained; and that the bacteriologic laboratory has done hitherto little, if anything, to enlighten this field of research. It is still to clinical experience that the physician must look for the knowledge which will enable him to recognize and combat this versatile enemy.

The arrangement of the subject is good, and will be found convenient by the reader. Chancroid is very properly assigned a separate chapter at the end of the book.

We note occasional awkward slips of style and stilted modes of expression. Thus on page 289: "Syphilis does not produce tuberculosis or rhachitis, though the latter has been affirmed of rhachitis by Parrot." And on page 663: "Enough has been said to substantiate the fact that it is not an irrelevant matter for a person to be adjudicated a syphilitic."

Perhaps the best article in this work is that by White, of Philadelphia, on the treatment of the disease; it is very full, clear, and practical, or as our English brethren are wont to say, helpful. Another of much merit is by Armstrong, on "Syphilis in its Relation to Public Health," and "Visceral Syphilis" is ably discussed by Councilman.

The illustrations are numerous, and for the most part very good; some of them are strikingly so.

A Text-book of Physiology. By Michael Foster, M.D., F.R.S., Prelector in Physiology in the University of Cambridge; Fellow of Trinity College, Cambridge, Eng. New (fifth) American from the fifth English edition, thoroughly revised, with Notes and Additions. In one octavo volume, 1083 pages, with 316 illustrations. Philadelphia: Lea Brothers & Co., 1893.

No better recommendation can be desired for a medical book than the knowledge that a large edition has been exhausted in two years. The fourth edition was published in 1891, and now the fifth comes to us, revised to date in all the branches of this fundamental science of medicine. Prof. Foster's text-book differs from others in that it attempts to impart a general knowledge of the human body before it begins to specialize the various functions. We all know how difficult it is to teach genuine physiology to students who have not had any previous instruction in the science, because the elucidation of almost any one of the physiologic phenomena presupposes the knowledge of one or more of the general features influenced by or influencing the subject under discussion, and in this respect Prof. Foster's book seems to take a step in the right direction. When a book is equally well written throughout in a fair conservative spirit, it is always difficult to select some one part, but we are glad to find in the chapter on Absorption a final definite statement which relegates the often quoted and often discussed *physical* diffusion and osmosis to well-deserved oblivion. Prof. Foster says: "Diffusion which takes place in a living cell is so different from ordinary diffusion through a dead membrane that it is undesirable to speak of it by the same name, for the passage of material through the pores of a living cell takes place according to laws quite different from that of ordinary diffusion." It is high time that the *physical* theory of life were left out of our medical text-books.

We can heartily recommend the book to the general practitioner as well as to the medical student; its typographic outfit is of the customary high standard of the publishers; the illustrations are numerous, many being original, and in spite of its 1100 pages it forms a volume of convenient size.

New York County Medical Association, State of New York. Register of Members: Manual of Information. New York: Printed by the Association, 1893.

This little publication contains an official list of the members of the New York County Medical Association for the year ending June 30, 1893, together with the names of other practitioners of rational medicine, thus making as complete a list as can be obtained of all regular physicians resident in the city and county of New York. In addition there will be found interesting information concerning the New York County Medical Association, the New York State Medical Association, the American Medical Association, the Pan-American Medical Congress, and International Medical Congresses. In the schism that exists in the profession of New York State, the County Association recognizes the authority of the Code of Ethics, and maintains its adherence to the American Medical Association. That the Association is in a flourishing condition needs no better demonstration than the fact that during the preceding year its membership was augmented by a net increase of 170. There remains but to add the warmest commendation for the course the Association has pursued.

CORRESPONDENCE.

AN OPPROBRIUM OF MEDICINE.

To the Editor of The Medical News,

Sir: The chief advance in medical science of late years has consisted, so to speak, in retrogression. This looks like a paradox, but in reality it is a statement consistent with reason, as I shall endeavor to show in a clear and conclusive manner.

At the commencement of the nineteenth century there was an opinion generally prevalent amongst the medical faculty, practically at least if not theoretically, that every disease possessed a distinct constitution of its own; that it was, in fact, a separate entity; a parasite, like the mistletoe, fattening on the life-juices of its involuntary host. Between many of the manifestations there were points of resemblance, and certain signs and symptoms were common to nearly all; but each malady nevertheless stood firmly on its own bottom; and was not to be mistaken for, or confounded with, any of its congeners.

The brain of a medical practitioner a hundred years ago might have been likened to a sheet of paper divided longitudinally into two unequal parts. On the narrow side there was a formidable string of names, representing

diseases; and on the other an equally portentous array of antidotes. The enemy's forces were enumerated *seriatim* on the left, and on the right there was inscribed a detailed list of the ammunition by means of which they were to be routed and destroyed. It is true that for each ailment in particular there did not exist a special remedy warranted to slay or at all events scotch the foe, but an attempt was made in the desired direction by combining many drugs in one lengthy prescription. The medical general fired off a salvo at the invader; bringing his case-shot to bear in the hope that some of the numerous missiles therein contained might reach the mark. If one missed, another might hit, and it was fervently hoped that, with luck, the daring intruder would be placed *hors de combat* as a result of the maneuver.

By slow degrees this happy-go-lucky state of affairs began to die away. Diseases ceased to be treated as though they were living creatures; the natural ills that flesh is heir to grew to be regarded as simply the result of a disordered system—whatever that might mean; and medicines, no longer esteemed as antidotes, fell completely into disrepute. It was the apotheosis of *laissez-faire*. Expectancy was the god of the moment, and masterly inaction became the order of the day. Here was change with a vengeance; but the triumph of the everlasting nay did not long endure. Reaction was inevitable, and it is under that reaction we are now suffering.

Disease has once more become an entity! Every separate affection has its own distinctive microbe—the cause of all the trouble, the *fons et origo malorum!*

This, many will think, is bad enough, but worse is to follow. Homeopathy, so long well-nigh moribund, is now absolutely rampant. The only way to combat these nocent microbes is by opposing them with armies of their own kind, in all probability equally mischievous. "Set a bacillus to catch a bacillus" is the cry of the *fin de siècle* physician, thanks to his researches in "the dead-house, the rabbit pen, and the laboratory."[1] Nature and the clinique are allowed to go by the board, and herein lies the opprobrium alluded to at the commencement of this article.

Having thus ended the general portion of my thesis, I crave permission to draw attention to one disease in particular, wherein no progress whatever has been made of late years, whether as regards etiology or treatment, in consequence, as I believe, of universal attention being directed toward microbes, and toward microbes alone.

The disease I refer to is deafness. It would be impossible to imagine an affection calculated to render life less worth living, but that is not the point I am at present anxious to elucidate. My object will, perhaps, best be attained by narrating a case which from personal knowledge I guarantee as perfectly authentic and unexaggerated.

Some two years ago the patient, who was then living in Egypt, first noticed, at the age of fifty-one, that he was slightly hard of hearing; having previously, all his life, enjoyed perfect possession of the sense, and being in fairly good health at the time. The deafness continued for about six weeks, in both ears alike; but it was very trifling, and did not in the least interfere with social intercourse. Then, suddenly, without any apparent cause, what he describes as "unbearable" tinnitus set in on the left side, the prominent feature being an exaggerated pulsation-sound, synchronous with the heart's action. This commenced during the night, and the next morning the sufferer was completely deaf in the left ear. The tinnitus gradually became less marked, and for ten days matters remained *in statu quo*. In the mean time, however, a medical man was consulted. He duly examined the ears and pronounced both drums intact, save that they were excessively indrawn and tense, with the ossicles projecting prominently. The treatment consisted in catheterization of the left Eustachian tube, with insufflation on both sides according to Politzer's method. There was no improvement whatever. Then the doctor proceeded to pass a catheter into the right Eustachian tube, and according to the patient the *immediate* result was total deafness on that side also, accompanied by what he describes as a sensation as though a fluid were being poured out into some cavity inside his right ear. Since then he has remained completely deaf on both sides. He can detect sharp metallic sounds readily, but is quite unable to hear the human voice even when it is conveyed through the most powerful trumpets or tubes. At no time throughout the case was there the slightest giddiness or loss of conciousness; neither did he ever experience any pain.

The patient then returned to England and consulted a well-known London specialist, who ordered him iodid of potassium in extra-large doses, with blistering, followed by a weak mercurial inunction, behind the ears. It must here be noted that there is no history of syphilis in the case; and the most careful examination has failed to reveal the existence of any traces of that disease. This treatment was kept up for three months, without the slightest benefit as regards the deafness, or the tinnitus which, it should have been mentioned, was the most distressing part of the complaint. The sufferer was then induced to consult another specialist, his friends being of opinion that the potash was gradually bringing him to death's door. The second professor made a most exhaustive study of the case, and came to the conclusion that the portion of brain presiding over the sense of hearing was at fault. He recommended phosforus; but the only result of a prolonged course of that powerful medicament was a totally unnecessary and undesired stimulation of the generative organs.

Having had enough of specialists, my subject next consulted a general practitioner who happened to be a great believer in iron as a universal panacea. He prescribed the tincture of the perchlorid with Epsom salts.

It must be allowed that this treatment, which was persevered in for a lengthened period, had a slightly beneficial effect on the deaf man's general health, but his local affection remained precisely *in statu quo*.

The next essay was electricity pure and simple, under the guidance of a specialist who said there was just a chance of its doing good if persevered in, but that the odds were greatly against it. For four long months the battery was duly applied twice a day for twenty minutes at each sitting, but the effect was absolutely *nil*. Since then the patient has abandoned all radical treatment in despair, nor am I able to suggest any medical course that

[1] Wallian: The Medical News, November 11th, 1893.

would seem to afford even the slightest hope of success. The tinnitus is the most troublesome symptom, but it is rendered bearable by opium. But for this truly named drug the unfortunate man says he does not think he could bear up against the incessant, brain-wearing noises.

The question I should like to ask now is: Would an operation afford any prospect of cure? Would washing out the middle ear be likely to give good results? The patient himself says that if, when the deafness first came on, his head had been shaved and repeatedly blistered, he believes it would have led to the absorption of the effusion which he feels confident has taken place somewhere inside his head.

I should have said that when the deafness first made its appearance my subject was exposed to a great deal of annoyance and worry. His eyesight and sense of smell are unaffected, and his general health and bodily activity quite unimpaired.

AN ANGLO-EGYPTIAN OFFICIAL.

NEWS ITEMS.

The Congress of American Physicians and Surgeons will be held in Washington, D. C., May 29, 30, 31, and June 1, 1894. The following preliminary program has been arranged:

May 29th.

3 P.M. Congress opened by the Chairman of the Executive Committee.

From 3.30 to 5 P.M. General Session of the Congress under the direction of the Association of American Anatomists.

"Morphology as a Factor in the Study of Disease." Opened with a paper by Dr. Harrison Allen, and discussed by Dr. Thomas Dwight, Dr. Frederick H. Gerrish, Dr. Frank Baker, and Dr. Burt G. Wilder.

May 30th.

From 2 to 3.30 P.M. General Session of the Congress under the direction of the American Climatological Association.

"Sewer Gas." The Bacteriology, by Dr. Alexander C. Abbott. As a Cause of Disease, by Dr. Abraham Jacobi.

From 3.30 to 5 P.M. General Session of the Congress under the direction of the American Dermatological Association.

"The Distribution and Control of Leprosy in the United States." The Distribution, opened with a paper by Dr. J. Nevins Hyde and discussed by Dr. William A. Hardaway and Dr. James E. Graham. The Prophylaxis and Treatment, with a paper by Dr. James C. White, and discussed by Dr. George H. Fox, Surgeon-General W. C. Wyman, U. S. M.-H. Service, and Dr. Joseph D. Bryant.

7 P.M. Dinner to the Guests of the Congress at the Arlington Hotel.

May 31st.

From 2 to 3.30 P.M. General Session of the Congress under the direction of the American Association of Genito-urinary Surgeons.

"Nephritis in its Surgical Aspects." Opened with a paper by Dr. Edward L. Keyes, followed by a paper from Dr. George M. Sternberg, Surgeon-General United States Army, on The Bacteriology of Nephritis, and discussed by Dr. George Chismore, Dr. L. Bolton Bangs, Dr. Francis S. Watson, and Dr. W. N. Wishard.

From 3.30 to 5 P.M. General Session of the Congress under the direction of the American Gynecological Society.

"The Conservative Surgery of the Female Pelvic Organs." Papers will be read by Dr. William M. Polk and Dr. William Goodell.

7.30 P.M. Address by the President of the Congress, Dr. Alfred L. Loomis, on The Influence of Animal Experimentation on Medical Science. To be followed by a Reception.

June 1st.

1.30 P.M. Business Meeting of the Congress.

From 2 to 3.30 P.M. General Session of the Congress under the direction of the American Laryngological Association.

"The Surgery of the Accessory Sinuses of the Nose." To be discussed by Dr. F. H. Bosworth, of New York; Dr. J. N. Mackenzie, of Baltimore; Dr. J. H. Bryan, of Washington, D. C.; Dr. J. O. Roe, of Rochester, N. Y., and others.

From 3.30 to 5 P.M. General Session of the Congress under the direction of the American Neurological Association.

"The Influence of Infectious Processes on the Nervous System." Pathology and Etiology, by Dr. James J. Putnam. The Relation to General Nervous Diseases, by Dr. E. C. Seguin. The Relation to Mental Disease, by Dr. Charles K. Mills. The Therapeutics, by Dr. F. X. Dercum.

Von Rosthorn has been made Ordinary Professor of Obstetrics and Gynecology in the German University of Prague.

A NEW AND SUCCESSFUL TREATMENT OF HAY-FEVER—THE VIEWS OF THE PROFESSION.[1]

By SETH S. BISHOP, M.D.,
OF CHICAGO

I HAVE endeavored to solve the perplexing question why attacks of hay-fever, or nervous catarrh, come on persistently the first thing in the morning on awakening from sleep. This happens even when the previous day has been one of immunity, and the night one of undisturbed repose; when there has been no change in the contents of the sleeping-apartments and no ingress of dust or air through any direct communication with the outside atmosphere.

I hope, but do not insist, that my studies and experiments in elucidating the cause of these attacks have resulted in solving this problem of hay-fever. If so, it will become apparent what an important advance we shall have made in the pathology and treament of this disease.

It is necessary to make this paper only an imperfect abstract of what I have prepared, for the following reasons: My desire to present the latest obtainable information on the opinions and treatment of the leading specialists and writers; the large amount of original observations and experiments and corroborative evidence I have accumulated; and the specified condition that the essay "must not exceed four thousand words."

Uric acid as a cause. Human blood is normally slightly alkaline and contains uric acid in the form of urates in small quantity, about five to eight grains being secreted every twenty-four hours. When a much larger quantity is secreted it is capable of producing irritation and inflammation of certain structures of the body, unless it is promptly eliminated. It is well known that uric acid has an irritating action on the nervous centers. Alexander Haig, of London, a sufferer from migraine, or sick headache, accounts for vertigo, convulsions, depression, irritability, sleeplessness, pains and neuralgia of varying sorts, migraine, paralysis, etc., by the excess of uric acid in the system. He regards the various functional disorders as a result of the vascular conditions produced by uric acid; and these views are concurred in by Thomas J. Mays, Murchison, Conklin, Ebstein, Quinquaud, and others. Haig studied, in his own person, the relation of uric acid to attacks of migraine, a functional nervous affection, and found that during the attacks the uric acid predominated in the blood. Its presence in excess accounts for exacerbation of pains in rheumatism and gout, and Lever contends that these diseases are primarily due to the action of this acid on the brain, the spinal cord, or the solar plexus of nerves.

In persons suffering from intense itching, uric acid and the urates are found in excess. Periodic sore-throat, which often comes on about the beginning of May, yields to anti-uric-acid treatment, or a change to a warm, sunshiny climate. This condition is analogous to hay-fever. The administration of from three to six grains of uric acid a day will result in patches resembling eczema, which I would term the dermal analogue of coryza. Common coryza, which might be aptly called the twin of hay-fever, may itself be accounted for by the irritating action of uric acid in excess in those individuals who are constitutionally predisposed to nasal irritation.

According to Dr. N. S. Davis, Murchison, and other authorities, the poisonous effects of varying degrees of excessive uric-acid formation or retention are manifested by one or more of the following symptoms: Headache, usually most severe in the morning, and often referred to the back of the head; want of appetite; nausea and vomiting; flatulent indigestion; diarrhea; asthma; blindness; deafness; subjective noises in the ears; numbness of the skin and creeping sensations; over-sensitiveness and pain in the skin; impaired memory; melancholia; delirium; insensibility (coma); and epilepsy. Familiar examples of some of these manifestations of uremic poisoning are seen in the loss of memory, in delirium, convulsions, coma, and death from chronic nephritis.

The pertinency of these remarks will become apparent in what follows. The blood is more alkaline in the morning than at any other time of the day, reaching its point of greatest alkalinity about nine o'clock. It is more acid during active work, and the acidity reaches its highest point about midnight. The uric acid is most liable to be in excess when the alkalinity is the greatest; that is, when the blood is in the condition of a more active solvent. This alkalinity of the blood and consequent pre-

[1] The Prize Essay of the United States Hay-fever Association for 1893.

dominance of such an irritant as uric acid, following the inaction of the night and preceding the bodily activity of the day, may answer the question why paroxysms of hay-fever, asthma, migraine, angina pectoris, and other nervous disorders prevail during the early morning hours.

ANTI-URIC-ACID TREATMENT.

Mineral acids diminish the amount of uric acid excretion and alkalies increase it. Acids relieve the headache of migraine and alkalies aggravate it. Haig found that diminishing the alkalinity of the blood freed it from uric acid, relaxed the small arteries, relieved the headache and mental depression. Increasing the alkalinity increased the uric-acid excretion, contracted the small arteries, slowed the circulation, caused languor, depression, headache, and, in epileptics, a fit.

Repeated examinations show that uric acid is excreted in larger quantities in warm than in cold weather, which may account for the greater prevalence of irritability of temper, depression of spirits and suffering from headache and hay-fever during the warm months.

The deductions I have drawn are founded upon proved scientific facts, for many of which I am especially indebted to Haig and to others whom I have mentioned. In the original of this paper I have taken pains to give each investigator ample credit by liberal quotations. I am obliged to omit these and give results only. Following out their logical indications I have experimented with an acid course of treatment in hay-fever; that is, I have endeavored to prevent the blood from reaching its maximum of alkalinity and the consequent uric-acid excess between midnight and noon, knowing that if attacks were prevented during this half of the day, immunity was more likely to be enjoyed during the remaining hours. This treatment stopped the attacks. To accomplish this I have employed mineral acids, although Bence Jones states that citric acid (lemon-juice) in sufficient quantities will produce the same effect. The results of this experiment have far exceeded my expectations. So far as the experience of one experimenter goes, the anti-uric-acid treatment I have inaugurated is a success. I began with the dilute sulfuric acid, from 10 to 30 drops in a wine-glass of sweetened water two or three times a day. It should be taken through a glass tube to prevent injury to the teeth, and the less sugar one takes the better. If this should produce griping pains and diarrhea, as I have known it to do, aromatic sulfuric acid may be substituted in the same doses. I might add that this is the best internal remedy against cholera. Another remedy, the acid phosfate of sodium, is also a good nerve-tonic. It should be taken in doses of one or two teaspoonfuls in a glass of water on retiring at night and the first thing on awaking in the morning. If nasal irritation appears during the day a good dose in plenty of water should be taken. Hot water can be used if one is chilly. The early morning dose should be the largest, and it is a decided advantage to take plenty of water, for this tends to stimulate the circulation, to produce a glow of warmth and to start a free perspiration. This is a very important point, for it is the experience of hay-fever sufferers that when they have sneezed enough to get into a heat and profuse perspiration, the sneezing decreases or stops. The acidulated drink for the morning dose should be prepared at bedtime and placed within easy reach, so as to be taken at once on awaking, without uncovering.

I would request that during the season of attacks the simple and harmless acid treatment here outlined be given a fair and faithful trial, and that everyone who does so shall communicate to me the results for the benefit of all in a future publication. I do not claim that this treatment will prevent suffering from other causes than the important one against which it is given. Avoidance of all other causes and treatment to meet other indications must not be neglected. I base my recommendation of this method, aside from the uric-acid theory of hay-fever—here offered for the first time, so far as I know—solely upon the beneficial results actually obtained from its use.

By neutralizing the acid phosfate, which was my first choice in these experiments, and rendering it alkaline with soda, and thus converting it into a ready solvent of uric acid, I have been able to precipitate hay-fever attacks, and, on the other hand, I have dissipated a series of hay-fever attacks and induced the characteristic pains of gout by full doses of the acid.

Preventive treatment. The treatment thus far laid down is for the periods of suffering only, and is to be followed up by other means to prevent the recurrence of attacks by keeping the amount of uric acid in the blood down to the normal. The solvent action of salicylate and phosfate of sodium on uric acid constitutes these the best remedies for promoting the elimination of this acid from the body. Uric acid may have been stored up in the liver, spleen, and other tissues for a long time, and through improper diet and indigestion there may have been excessive formation, though Haig denies the latter proposition. I believe both theories to be correct, and in a conversation with N. S. Davis he expressed the same conviction. If the blood is rendered more alkaline it dissolves the excess of acid out of the tissues, and sweeps it out of the body through the kidneys and skin. The salicylate

of sodium should be taken for this purpose in small doses for a considerable time preceding and following, but not during, attacks. For example, if the attacks come on the 20th of August, doses of 2, 4, or 6 grains of the salicylate from one to three times a day, should be begun forty days before. As much as possible, meats, sweets, beers, wines, etc. should be avoided and the diet limited mostly to milk, fruits, vegetables, and fats, such as butter, etc. I do not insist on this rule except in severe cases, but it illustrates a diet that is less productive of uric acid. During eight years of this diet Haig was able to prevent his sick-headache, but a few days of indulgence in the prohibited diet was invariably followed by headache.

I will say parenthetically that I have obtained the gratifying results referred to without paying any attention to the question of diet. Lithia water freely taken aids elimination by converting the uric acid and the more insoluble urates into a soluble salt and stimulating the kidneys. Probably the large amount of water usually taken is an important factor.

Since writing what I have on uric acid in hay-fever, I have learned that Leflaive, of Paris, has found uric acid in great quantity just before the attack and half that quantity during the attack. In sick-headache Haig found it as 1 to 40 of urea before and after attacks and 1 to 20 or 25 during attacks. This variance is naturally accounted for by the rapid elimination of uric acid during the violent muscular exertions, profuse sweating, discharge of mucus, etc., during the paroxysm of sneezing. There are no such corresponding exertions and increase of secretions, mucus, sweat, etc., during the headache.

For local treatment patients have found much relief during attacks by using an inhaler, like that

shown in the illustration, which can be carried in the pocket, and contains a 20 per cent. mixture of equal parts by weight of camphor and menthol. It has a more soothing and correcting effect on the nerves and vessels than menthol alone. It does not become irritating, like menthol crystals, after being used for some time. It can be used unnoticed in public places the instant any irritation appears, and thus prevent or cut short attacks. Three or four slow, deep inhalations should be taken from it in one nostril, while the other is closed, until the irritation is relieved. The breath should not pass back through the camenthol inhaler, but out through the mouth instead. To treat the throat and bronchial tubes it should be inhaled through the mouth.

Medical opinions. I have written to a large number of specialists and writers on this subject to obtain their latest views and treatment. There were some whose recent publications made it unnecessary to write, and others who were inaccessible in the very short time allowed (five weeks) for gathering and transmitting this information. So I have in such cases searched the literature, and have endeavored to present a fair and impartial account of the present status of medical opinion on the nature and treatment of hay-fever. From some articles I have been unable to gather any definite knowledge of the opinions of the writers on the nature of the disease, and have stricken out much for that reason, but I have in every case presented striven to give a natural and unbiased interpretation of the author's views. The methods of treatment often indicated these. All titles will be omitted to save space, and the opinion of each writer on the pathology, whether he believes it to be a neurotic or local affection, will be indicated by a single word following his name—*neurosis*, or *local disease*.

It so happened that the first answer received in response to my letters represented the views of a large proportion of conservative surgeons in diseases of the nose and throat so fully that I give it first place in this collection. It was necessary to abbreviate it by omitting the more technical passages. It is from my good neighbor, W. E. CASSELBERRY.

Neurosis. "I believe hay-fever to be amenable to thorough surgical treatment, establishing a complete cure in a minority of cases only, those particularly which present gross deformities of the septum and the turbinates, and polypi. In the large majority the condition can be materially mitigated, the degree of improvement being in accordance, first, with the degree of structural disease present in the nose; and, secondly, with the thoroughness of the treatment. A small minority are not amenable to surgical treatment. They include the highly neurotic individuals in whose noses, between the paroxysms, little or no structural change is apparent. Much can be accomplished toward palliation by both systematic and local medicinal treatment. But in my experience medicinal treatment is nearly, if not quite, powerless to effect a permanent cure. Such, however, may take place in the course of years, perhaps, assisted by supportive and tonic treatment, as the individual's general health improves and the neurotic element lessens. Of local palliative remedies, cocain is probably the most powerful and at the same time the most dangerous remedy. Its use and sale should be regulated by law."

E. L. Shurly. *Neurosis.* "I am very glad that you will present the subject of the treatment of hay-fever. It is a very important one, and does not receive the intellectual attention which it deserves. It is my belief that some cases can be relieved by counter-irritation in almost any part of the body, as well as in the nasal passages. I also believe that its purely nasal origin is overestimated. I have found snuff of daturin with starch sometimes more effective than the galvano-cautery." He uses tincture of iodin, etc., over the neck and chest, as recommended by Faulkner. If there are new growths he removes them.

C. H. Knight. *Neurosis.* Destroys all enlargements. "When it is impossible to define a distinct abnormality, the nasal membrane throughout being sensitive and irritable, good results seem to me to follow painting the mucous membrane with a solution of perchlorid of mercury, muriate of quinin, and glycerite of carbolic acid. Of course, general treatment is always essential. I must confess that my proportion of cures is small. I feel quite pleased if I succeed in mitigating the severity of the symptoms and lessening their duration, etc."

W. C. Glasgow. *Neurosis.* "Surgical treatment has given little or no permanent relief. Symptomatic treatment will ameliorate the symptoms and keep the patients in comparative comfort during attacks. The constitutional treatment with potassium iodid, belladonna, antipyrin, etc., lessens the disturbance and sometimes controls it."

Jonathan Wright. *Neurosis.* "I have seen several cases with no appreciable intra-nasal lesion except the acute condition during the attack. I have operated a few times for intra-nasal lesions of various kinds. All were improved somewhat, some markedly, some slightly. My impression is that the relief in these cases is too limited to make it of value."

R. W. Seiss. *Neurosis.* Operations in the nose should be resorted to cautiously, and only when absolutely necessary. He recommends strychnin and bromids internally, and benzoate of sodium, 10 to 20 grains to the ounce, or menthol, 10 to 30 grains, for a spray.

E. J. Kuh *Neurosis.* A sufferer from hay-asthma. He found the most relief from the following spray: Camphor ½ part, menthol 1 part, creosote 1, oil of eucalyptus 2, oil of pine-needles 2, albolene or benzoinol 93½ parts.

J. O. Roe. *Local.* He believes that there is always a diseased condition of the nose causing hay-fever. These diseased tissues must be removed or destroyed. He denies the neurotic character of the disease. He says: "Irritation reflected from other situations to the nasal chambers is not hay-fever." (Then what is it?)

F. H. Bosworth. *Neurosis.* He believes that intra-nasal surgery affords permanent relief. This method is clear in its indications, easy of accomplishment, and promises not only more immediate but more permanent relief than any other method. He believes that hay-fever and spasmodic asthma are pathologically identical.

J. N. Mackenzie. *Neurosis.* Better results were obtained from constitutional than from local treatment. He gives zinc, nux vomica, quinin, and arsenic.

W. H. Daly. *Local.* He thinks it is simply a deformity in the nose and that a large proportion of cases can be cured by surgical operations.

J. Solis-Cohen. *Neurosis.* Any local nasal trouble may be simply incidental. He prescribes tonic treatment and restricts the use of meat.

H. Gradle. *Neurosis.* He removes any nasal growths.

Kitchen, of New York. *Local.* He believes it is due to the membrane being deficient in the epithelial covering, etc., that calls for local remedies.

B. O. Kinnear. *Neurosis.* He believes it to be due to irritation of the gray matter composing the centers of the fifth, glosso-pharyngeal, the facial nerves, and some of the pneumogastric. He found that treatment addressed to this condition was successful. He used the well-known ice-bags of J. Chapman, of Paris, along the spine between the shoulders, from the fourth cervical to the third dorsal vertebra, to dilate the arterioles of the whole body, thus evenly distributing the circulation and withdrawing the blood from the congested centers. The applications lasted from 60 to 90 minutes, 1 to 3 times a day.

E. F. Ingals. *Neurosis.* About 40 or 50 per cent. of cases may be cured by cauterization. He has modified his views of eight years ago, when he thought that nearly all could be cured by burning. He gives tonics, and cocain locally.

M. R. Brown. *Neurosis.* The supersensitive areas should be destroyed with the cautery. Atropin, $\frac{1}{100}$ grain, once or twice daily, or a 4 per cent. solution of cocain locally may give temporary relief.

H. H. Curtis. *Neurosis.* He sears the enlarged tissues with chromic acid in preference to all other escharotics.

C. E. Sajous. *Neurosis.* He believes that if cauterization fails to cure, it is because it is not carried deeply enough. He uses glacial acetic acid, or nitric acid. He gives strychnin and coca wine after meals.

William Cheatham, of Louisville. *Neurosis.* He praises antipyrin in 10 to 30 grains, also acetanilid, 4 to 6 grains a day.

T. M. Hardie. *Neurosis.* He believes that operations will benefit a large proportion, but constitutional treatment is necessary in most instances.

J. R. Davey. *Neurosis.* He removes enlargements and gives potassium iodid and tonics.

Beverley Robinson. *Neurosis.* He uses soothing applications and constitutional medication. He advises against surgical interference except when there are positively diseased growths.

I. Gluck. *Local.* He believes the nervous element to be a result, instead of the cause, of the disease. He uses a 10 per cent. solution of atropin after anesthetizing with cocain-phenol. He gives aconitin every hour or two, affording relief and aborting attacks in from two to five days.

Carl Seiler. *Neurosis.* He uses sprays of

cocain and plugs of cotton saturated with it. A sponge worn in the nose to filter the air is recommended. Quinin in large doses is advised and tonics and atropin for the fever. In the later stages iodid and bromid of sodium are given. Morphin hypodermatically is advised. All enlargements should be removed; he gives dilute phosphoric acid —30 drops a day.

De Lamalleree. *Neurosis.* He believes it a neurosis of nasal origin, and claims to subdue morbid sensitiveness of the membrane by douches of carbonic acid gases locally for fifteen minutes at a time, three times a day.

Sir Andrew Clark. *Neurosis.* He resorts to constitutional remedies and applies to nostril with a camel's-hair pencil this mixture: 1 ounce each of glycerin and carbolic acid, 1 dram of quinin, and $\frac{1}{2000}$ part of perchlorid of mercury. Heat must be used to dissolve the quinin.

P. McBride. *Neurosis.* He treats it as a nervous disease, and if this fails he uses cocain and the galvano-cautery. He deprecates indiscriminate burning, however.

D. B. Lees. *Neurosis.* He claims to abort it with bromid and belladonna.

Gouguenheim. *Neurosis.* He uses nervines and cocain locally.

The writer of this paper operates with the galvano-cautery or by other methods when there are positive indications for such measures.

The limits of this essay having been reached, all remarks of a generalizing character on this array of medical evidence will be omitted.

DEATH IN THE NILE.[1]

By DR. GREENE PASHA,
OF KNAPHILL, SURREY, ENG.

As blood is the life of man, so the river Nile is the life of Egypt. While the first remains thin and wholesome, circulating freely throughout every organ and member, and capable of self-purification by reason, in a great measure, of its rapid motion, the fortunate possessor enjoys good health; but if from any cause, inherent or acquired, the flow of the vital fluid be retarded, and the faculty of getting rid of effete and poisonous material be thereby interfered with, he will sicken and die.

This is equally true with regard to the river. As long as the current continues sufficiently powerful to sweep away impurities—before there is time for them to develop their lethal properties—the people thrive; but no sooner does stagnation, however brought about, set in, than at once the death-rate becomes an index of the degree of fouling the water has undergone, the extent of the pollution which the current can no longer cope with.

The reason for the annually recurring holocaust in Egypt is writ so plain, that he who runs might read; but such is the power of habit, so inveterate is the apathy attendant on custom, that no attention whatever is paid to a condition of things as disgraceful as it is lamentable. The foul fiend of usage has blinded the eyes of those in whose hands is the remedy, and no one in authority will endeavor to set right what prejudice will not allow him to acknowledge as a wrong.

In Egypt there is no water, potable or the reverse, except the stock supplied by the Nile. There is not a single natural spring in the whole country. So-called springs and wells are fed by infiltration from this wonderful river, which drains a surface as extensive as Russia, and for the last 1200 miles of its course receives no affluent whatever, great or small. A glance at a map of Egypt, as now constituted, will suffice to show that the population is truly riparian; the seven or eight millions of inhabitants all dwell within easy reach of the Nile, including its branches and canals, and nine-tenths of the putrescible filth they produce are cast into its bosom.

This is of course abominable, but the reprehensible practice has now gone on for so long that the desecration of the sacred stream is no longer looked on as a sin by the, in this respect, unworthy descendants of the most hygienic nation of antiquity.[1]

When it is considered that the fall in the bed of the river from Assouan to Cairo is only between two and three inches per mile, and that throughout the Delta even this infinitesimal slope diminishes to less than one inch per mile, it will readily be perceived how easy it must be to bring about stagnation during the low-Nile season. It is the custom at that time to bank up the water in hundreds of impure reaches, for the sake of the crops. The fields must be watered or the revenue could not come in; irrigation has to go on *quand même;* but the current, already well-nigh moribund from natural causes, soon dies outright.

[1] [The author was seven years head of the Egyptian Sanitary Department, and obliged to retire by sudden and total deafness. —Ed. Medical News]

[1] "The ancient Egyptians had two chief gods—Horus and Ammon. The first was usually depicted as the sun; the second was the spirit of the Nile. While worshipping and respecting these gods, as represented in their incarnations, Egypt was supreme and conquered the greater portion of the known world: but in these degenerate days your beautiful country is no longer mistress, and you may seek the reason in the scorn and contempt with which both these deities are treated. The utmost efforts are everywhere made to exclude the life-bestowing sun, and his attendant, air, from dwellings; and no filth is too foul to cast into the great life-sustainer, the sole water-supply of Egypt—the Nile!"

This quotation is taken from a letter written in September, 1890, by the Director of the Egyptian Sanitary Department to the minister who was then, and is still, at the head of affairs. It speaks for itself: and if no extract from the answer be appended, it is for the simple reason that none was received. The document, most probably, was never even read, and no doubt it was promptly consigned to that very capacious receptacle, the ministerial waste-paper basket.

No sooner has this regrettable but under the circumstances inevitable result taken place than the water begins to emit a nauseous smell, and on still days an iridescent scum may be seen covering its surface as though petroleum had been poured upon it.

Vital statistics in Egypt are not so perfect as in Europe or America. The officials of the Sanitary Department do what they can to collate trustworthy records, but they are terribly handicapped for want of a census. In 1882, during Arabi's so-called rebellion, an attempt was made to establish an enumeration of the people, but it was practically mere guesswork; and for all scientific purposes the pretentious volume in which the results are tabulated is absolutely without value.

The rates shown in the accompanying table cannot therefore be accepted as really representing the mortality in the various towns; but the figures serve for the purposes of this paper, as they demonstrate with the utmost clearness the extreme unhealthiness of communities drinking Nile water during the summer, and the relative salubrity of the two towns where alone the people are compelled to store up the pure flood-water in cisterns, or as they are called locally, *sahariqs;* their proximity to the sea rendering the river brackish when its level falls.

The table is almost self-explaining; a few remarks only are necessary to bring out the special points. The four weeks ending about the 2d or 3d of April may be considered the commencement of the low-Nile season, for at the end of the period there is usually very little current left. The river generally begins to rise in the early days of August, but a week or two naturally elapse before any improvement appears in the death-rate. It will be seen that the average mortality for the five years in the ten towns using water direct from the river or canal was in every case higher at the end than at the commencement of the season, the average rate of increase being equal to 53 per cent. Taking the towns, year by year, it appears that this phenomenon was observable forty-two times out of a possible fifty; and it is worthy of remark, though not shown in the table, that in the same towns the deaths exceeded the births during the low-Nile period thirty-eight times in the five years, whereas at Damietta and Rosetta the births were invariably far the higher.

These facts ought to be sufficient to convince most people that the water of the Nile becomes poisonous during the summer. But there is, unfortunately, still stronger evidence. In 1891 a canal on a higher level than the river was opened to Rosetta, and, for the sake of economy, the public *sahariqs* were allowed to remain empty. The con-

TABLE SHOWING THE RELATIVE MORTALITY IN EGYPTIAN TOWNS WITH AND WITHOUT SAHARIQS, TOWARD THE COMMENCEMENT AND AT THE END OF THE LOW-NILE SEASON.

N. B.—The rates are based on the census of 1882, which is notoriously incorrect, but the relative values are trustworthy.

DEATHS PER 1000 PER ANNUM.

Years.	Periods of four weeks ending respectively 22, 21, 19, 18, and 17 April.												Periods of four weeks ending respectively 12, 11, 9, 8, and 7 August.

sequences were simply disastrous. The ancient port, so long renowned as the most salubrious town in Egypt, at once fell from the post of honor, and ever since has occupied a position in the sanitary returns only a little higher than the average. The low-Nile season, which used formerly to be the healthiest part of the year, is now marked by the rise in mortality customary elsewhere; and the fatal influence of the deadly canal is also amply demonstrated by the unprecedented fact that the deaths now habitually exceed the births during the summer.

The reason the annual slaughter excites so little attention is because it is only the children that die. The innocents perish, but the withers of the adults are unwrung. In their infancy they pass through the ordeal, and are now immune to the effects of the poison.

It is as true of nations as of men that in their affairs "there is a tide which, taken at the flood, leads on to fortune." In the lives of peoples there are occasions when the events depending on prompt decision and prudent selection are of such incalculable importance, not so much perhaps to themselves as to their posterity, that vacillation and ignorant action at the critical moment are alike fatal. As a rule, the march of events in a country is a jog-trot affair, allied to the goose-step, and devoid of salient incidents to serve as landmarks for time; but now and again the level sequence of monotonous days is dislocated, and opportunities offer which, if neglected or misused, conduce eventually to ruin.

A crisis of this nature is now at hand in Egypt. It has nothing to do with politics, properly so called. It is not a petty ephemeral question such as the fall of a cabinet, to be invested with exaggerated interest one moment and forgotten the next. On the contrary, it is a real, solid question; one directly affecting hundreds of thousands of lives, and indirectly enormous sums of money. There ought not to be any doubt which of these two things—life or money—is of most importance; and yet it must be admitted that were not filthy lucre mixed up in this matter, there would be but little prospect of its ever attracting aught but an infinitesimal portion of public attention.

The question, shortly, is this. In February, 1894, an International Commission is to meet in Cairo to consider plans that will be submitted to it for increasing the supply of water furnished by the Nile during the three or four months when, its level having fallen, the current almost ceases. To most people this at first sight might appear to be merely a detail connected with irrigation, to be determined by engineers specially trained in that branch of their profession; but though, no doubt, irrigation is a subject of great importance in an arid, rainless climate, still it pales into insignificance before what in reality is the vital point, the very essence of the matter with which the Commission will have to deal.

For the purpose of watering the land in order that crops may grow, any water will suffice; in fact, the fouler it is the better will be the result. But when, at the same time, the drinking-supply of a people is concerned, the question of purity should take precedence of every other consideration.

The projects to be considered by the International Commission are practically two in number. One, which seems to be favored by the powers that be, consists in "ponding up" the river in its own bed at one, two, three, or more places, including, according to Mr. Willcocks, "poor and uninteresting" Philæ. The other project is that of Mr. Cope Whitehouse, in the Raiyan desert.

To a sanitarian the river ponds are absolutely indefensible. In the first place, the pure Abyssinian mountain water would all be allowed to flow through before the ponding-up began. The sluices would not be closed till January in each year, and the slowly-filled ponds would consequently owe their supply to the fever-stricken swamps of Central Africa. During its detention behind the barriers there would be ample time for the countless germs contained in this water to develop and come to maturity, and in this natural process they would receive the assistance of the putrescible matter continually being cast into the stream from Khartum downward.

There is not a single good word to be said in favor of the ponding-up scheme. Were no other plan available, the favored project might be accepted as a *pis aller*—as a palliative better than nothing at all; but it never could be looked on as a remedy for the evils exposed in the preceding remarks. It would be a sign of insanity if a starving man were to deliberately choose a broken fragment when he was offered an entire loaf, and yet this is practically what will be done if the ponding-up project be accepted.

In the Raiyan desert, far from all possibility of contamination, there is a vast hollow where the cream, so to speak, of the Abyssinian flood can be stored till required for use. Then let this be done! In the interests of poor humanity let us see all petty jealousies cast to the winds. Then will Egypt be indeed blessed with the most perfect scheme that has ever been proposed for her rehabilitation. It might, and ought to, have been carried out years ago; but better late than never. The critical moment has arrived, and on the decision of the Commission now depends, not only the prosperity, but the very lives of a hard-working, admirable people.

TREPHINING AS A CURE FOR TRAUMATIC EPILEPSY.[1]

By JOHN T. CHAPMAN, M.D.,
of Bessemer, Ala.

In these days of venturesome exploits in the fields of surgery, no greater boldness is perhaps displayed than when we propose to invade the very domain of thought and trespass upon her territories in search of disease. The temerity concerning the legitimacy of such encroachment has created adverse opinions as to the value of the operation of trephining for the cure of traumatic epilepsy. It is true that the proper knowledge of function-localization, when the operation was performed without success, was a prime factor. I wish to put myself on record that no one should undertake to trephine unless he understands the symptomatic localization of such lesions. It is true that trephining has been employed from the earliest times, and that the dura has been incised in many cases by older surgeons, but not until the nineteenth century has attention been directed to cerebral localization and to certain surgical procedures founded upon the indications that it has afforded. Such operations upon the brain have been conspicuously successful, and have been justly reckoned among the triumphs of modern surgery. When guided by the disclosures of pathology and physiologic experiments, and aided by the application of recognized aseptic laws, operations upon the brain have been devised and successfully executed, which in the immediate past would have been not only impossible but incredible; but it is equally true that these operations are still limited in number and application. The instances in which brain-lesions can be accurately defined and located, and afterward made subjects of operation with success, are comparatively infrequent.

The lesions that are of such nature, so well-defined and outlined, or so situated, in view of the demonstrated localization of brain-functions, that their diagnosis can be made with reasonable certainty, are few enough in the first instance; those that are in reach of the surgeon's knife are fewer still, and those in which the patient ultimately survives constitute but a small portion of the original scanty number. It is not strange, however, that these operations should fascinate by their audacity, and that when successful they should dazzle the modest workers in the more prosaic fields of labor.

It is also possible that the order with which the diagnosis of local lesions of the brain has been pursued, in the light of functional localization, may tend to distract from those general pathologic conditions that are of so much greater frequency.

[1] Read before the Southern Surgical and Gynecological Association, November, 1893.

It is just here that we must recall the property inherent in the cells of the cerebral cortex of manifesting, under the slightest stimulation, the phenomenon of automatonism, and often spontaneously; this is an important biologic condition of the cortex. It explains how contraction of the epileptiform convulsive nature may for a while persistently recur, even though the primary cause that obviously excited the true epileptic paroxysm—such as a piece of depressed bone, a tumor, or a clot—has been wholly removed. Manifestations that at first depend upon the advent of afferent impressions may afterward continue irregularly to emanate almost spontaneously from cortical centers that have been excited, from some eccentric source, to abnormal activity through long-continued, frequently-repeated vehement impressions. Through inter-cortical connection more than one center may participate in radiating the afferent impulses far beyond the special motor area primarily involved; while the primitive diseased focus itself continues to accumulate cell-force that is irregularly, but often paroxysmally, dissipated. Increment of energy doubtless depends upon the very metabolic tissue-changes that have occurred through hyper-nutritive processes in the nerve-substance or nerve-protoplasm, changes that for a period are all-sufficient and quite prone to keep up those automatic explosions. But let us for a moment suppose these automatic centers separated or cut adrift from all afferent influences; then, the usual source of normal stimulation being removed, all excitor-reflex expressions will wane away into undulation, slowly diminishing in frequency and vehemence until, coming gradually to a standstill, they gradually disappear.

Now from this physiologic view of the spontaneous intrinsic life-history of the brain, I feel prepared to maintain that when no disorganization of the cortex has yet taken place, surgical interference at the seat of injury with the trephine-elevator, or rongeur forceps, must assuredly cure the patient, as we release the cortex from all direct or threatening source of irritation. Let no recurrence of convulsive attacks particularly disconcert us; even should these nerve-symptoms continue for awhile, nay, even for a year, diminishing in intensity, experience has more than once shown that we may often look forward to a cure, but frequently still to amelioration of the symptoms in the nature of the paroxysm. I believe that if the record of cases of trephining for the cure of traumatic epilepsy were postponed until time rectified our misconception respecting them, we should realize more frequently the accuracy of this assertion. D. Hayes Agnew, in an article on the "Present Status of Brain-surgery," concurred with Mr. Horsley, that it was not proper to call a patient cured until five years after operation. This is just; but Agnew further adds that traumatic epilepsy is practically incurable

by surgery, and that a considerable number of such cases had better be relegated to the domain of medicine. Is it a wonder that we should hesitate to enter the domain of thought and trespass on her territory in search of disease when we have such authority relegating it to the domain of medicine? And yet, in spite of this, clinical experience has taught us otherwise.

Since the advent of aseptic methods, trephining may be regarded with less apprehension by the timid. Its propriety may now be decided simply in view of its probable advantage, or its more probable futility. It may be counted quite as safe as the use of the exploring needle in suspected abscesses, and safer than exploratory celiotomy. So far as subsequent danger or inconvenience from hernia cerebri is concerned, I may report with Horsley that in the surgery of to-day it has ceased to be an intimidation to the surgeon.

I believe this operation should be performed in every case of depressed fracture, when elevation and thorough exploration cannot otherwise be accomplished. It is doubtful if such operations (unless from want of proper knowledge of cerebral localization) have been known to do harm when they have failed to do good. It is certain that harm has come in more than one instance, when, because of general symptoms, operation has been neglected. It is impossible in recent brain-lesions to say what extensive comminution of the internal table may not exist. It is the possibility of the smallest bony spicula penetrating the brain and causing serious nervous disturbances in the indefinite future that demands the thorough examination of every cranial fracture. It should be held obligatory on precisely the same ground as the examination and cleansing of the external soft parts. The observance of such precaution is free from danger; its neglect may lead to either present or future serious complications.

We are prepared, then, to say that, in interfering surgically for the relief of epilepsy, we have encountered no peripheral source of trouble in any morbid condition that has confronted us. It is our duty from present enlightenment on the subject to determine, if possible, the brain-territory that disease oppresses, and to reach the disease before we hasten to declare that the trephine has discovered no disease, and proved powerless to relieve. A question aptly suggestive in this connection at once arises, whether indeed bold invasion of the diseased or supposed diseased province of the brain itself should constitute a legitimate step of the operation? If we are not to stop short of the successful fulfilment that the operation proposes, I unhesitatingly reply in the affirmative, of course qualifying this answer by an assurance that the distressed centers have been satisfactorily ascertained by the symptoms present and by application of electrodes with proper precaution. It is true that the procedure has not always been satisfactory, but it seems to be the rational course. One of the most impressive illustrations of what I have tried to show, trephining as a cure for traumatic epilepsy, is a case reported by Michael. I cannot forbear detailing this case.

More than forty years ago a lad of fourteen years of age, living at Charlotte, N. C., was kicked by a horse on the right side of the forehead, remaining unconscious several days; the frontal bone was fractured and depressed, and escape of pieces of bone kept the wound open for one year; cephalalgia interrupted his collegiate course, which he ultimately completed. Convulsions declared themselves later on, daily augmenting until his memory and general health became sensibly impaired. The fits, in number and violence, were so great that on one occasion he fell out of bed and dislocated his shoulder. He was operated on, an inch-and-a-half button of bone being removed at the seat of the injury. It presented on its cerebral surface an osteophyte an inch in length, adherent to the dura, which, when raised, exposed a visibly large absence of brain-substance involving the supra-frontal, mid-frontal, and sub-frontal gyri. Convulsions occurred the day after operation, and were repeated with singular vehemence for weeks. The tormenting headaches and mental decadence seemed ameliorated, however, though for months afterward epileptic attacks hopelessly depressed him. This operation was performed in 1855. The boy returned to his home eight years afterward. Michael, unexpectedly saw him again while he was serving, completely relieved, in the ranks as a private soldier and undergoing all the hardships of the tented field.

I operated on a boy, fourteen years old, who some three years previously received an injury of the head by a blow fracturing the parietal bones; three weeks after the injury he began to have epileptic convulsions; at the time I saw him the convulsions had become more frequent and more violent; the day before operation he had six such seizures. Two buttons of bone were removed at the seat of injury; there was considerable pressure from depressed bone; the membranes were hard and indurated. The indurations were cut out and the edges of the dura brought together by continuous catgut suture; drainage and dressing were aseptic. The wound healed almost by first intention. For two months after the operation the boy continued to have convulsive seizures, but they gradually decreased until they stopped four years and a half ago. He is now eighteen and a half years old, weighs one hundred and seventy pounds, and is working in a foundry where the temperature ranges from 110° to 120° F.

In conclusion, let me add that the doctrine that depressed fracture of the skull without symptoms requires no operative interference, a doctrine which in the past has been deeply rooted in the professional mind, I hold to be responsible for many, very many,

of the unfortunate sequels of head-injuries. However small may be the depression that follows a fracture of the cranium, save in one or two locations, it will encroach enough upon the dura to cause more or less irritation; though insufficient at first, and not at all recognizable to the consciousness of the patient, yet eventually that irritation will be propagated to the meninges and ganglia until finally the paroxysmal explosion occurs, and then, even when the initial lesion is removed, the slowly-established habit created by years of excitation will for some time remain. No amount of foresight can determine what will happen to the inside of the skull after the reception of an injury, from inspection of its exterior surface, the physiologic properties of the two being so very unlike. Whenever, therefore, in my judgment, the profession can accept the doctrine that all depressed fractures of the cranium, however slight may be the depression, are, entirely independent of pressure-symptoms, proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases.

SOME INDICATIONS FOR AMPUTATION OF THE LEG.

By F. F. BUNTS, M.D.,
PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY, MEDICAL DEPARTMENT OF WOOSTER UNIVERSITY, CLEVELAND, OHIO.

In presenting the subject of amputation of the leg, I do not desire to convey the impression that I consider what I am about to say as in any degree essentially new, but rather to emphasize certain indications that seem to call for amputations of the leg other than those most commonly found in works on surgery.

1. I consider any injury to the foot, so severe as to permit only of a Pirogoff, a Symes, or a Chopart amputation, to be an indication for amputation of the leg in the lower third.

2. Tuberculosis of the tarsal bones, except in children, should, with few exceptions, be regarded as an indication for amputation of the leg in the lower or middle third.

3. Those extensive wounds and burns of the soft parts in which large portions of the integument and soft parts are destroyed, leaving the bone covered only by an extensive and tender cicatrix, demand amputation.

4. Senile gangrene of the toe or foot demands amputation of the leg or thigh above the bifurcation of the popliteal artery.

5. Shock, dependent upon a severe injury to the leg, when it is obviously impossible to save the limb, should, if reaction do not take place in a short time, be an indication for immediate amputation.

The first indication, that in which a Pirogoff, a Symes, or a Chopart amputation might be performed, is one which has been forcing itself upon the profession with increasing strength from year to year.

The destruction of the arch of the foot, the uncertainty of obtaining useful stumps, the inability satisfactorily to adjust mechanical substitutes for the portion lost after either of these operations, seem to me to justify our recommending an amputation at this time, rather than to be obliged to see our patient forced to rely upon crutches, unsatisfactory and awkward substitutes for the foot, and most likely to undergo an amputation before he can have fitted a limb at all useful or comfortable.

That amputation for suppurating tuberculous disease of the tarsal bones in adults will not be accepted by a great many as an indication for amputation of the leg, I am well aware, and yet the treatment of this disease has been so uniformly unsatisfactory that I believe it should be considered an indication in most cases for amputation, rather than to allow the patient to continue with a practically useless foot, or to run the well-established risk of general tuberculous infection.

We have all, perhaps, seen those extensive wounds of the soft parts of the leg and foot in which cicatrization has been eventually complete, and yet in which, owing to extreme sensitiveness, or to the repeated occurrence of large and intractable ulcerative processes, amputation has been rendered necessary after years of suffering, or of disability. In those cases in which we can foresee such a result, we should not let the importunities of the patient to save his leg blind us to the ultimate consequences, or to the propriety of advising amputation, and then allowing the patient to take upon himself the responsibility of the future. I am well aware that I am trespassing upon debatable ground when I advocate amputation of the leg above the bifurcation of the popliteal artery in senile gangrene below that point, but I feel sure that by its early performance the patient has a better cha ce for life and usefulness, suffers less pain, and runs less risk of septic poisoning than by that method that tells us to fold our hands and wait for the line of demarcation to form.

It is doubtful whether my last indication for amputation should technically be enumerated here, but what I wished particularly to call attention to was, that a patient suffering from severe shock as the result of a crush of the foot or leg, and who fails to react satisfactorily after not to exceed half an hour of intelligent efforts directed toward restoring the circulation and body-heat, will, if he be not in a moribund condition, stand a better chance of recovery with an immediate amputation than by delay. Reaction will not be delayed by the operation, but the continued presence of a crushed and mangled limb will rather tend to perpetuate shock and render

sapremia and septicemia more probable than a prompt and bloodless removal of the part

In presenting for consideration these indications for amputation, I have, for various reasons, purposely avoided referring to statistical evidence. Statistics, especially medical and surgical statistics, are capable of so many op osite interpretations, that they are often not only capable of carrying erroneous impressions, but may be absolutely dangerous. Nor have I related cases illustrative of the various propositions stated, though I have considerable material for such illustration. I have rather preferred to state them briefly as the result of my clinical experience, satisfied that had I appreciated them fully at an earlier date I might have saved much suffering, and I believe a few lives.

I trust that if any feel called upon to criticise these indications they will do so, using as a base their clinical experience, and not statistical compilations.

ORIGINAL LECTURE.

CONGENITAL PTOSIS—TRAUMATIC PARALYSIS OF THE LEG—NEURITIS FOLLOWING INFLUENZA—SPASM OF MUSCLES OF THE FOREARM, WITH TROPHIC CHANGES.

By HAROLD N. MOYER, M.D,
NEUROLOGIST TO COOK COUNTY HOSPITAL; ADJUNCT PROFESSOR OF MEDICINE, RUSH MEDICAL COLLEGE, CHICAGO.

PTOSIS PALPEBRÆ SUPERIORIS CONGENITA.

THE patient presented to you to-day shows a most striking deformity. As you look at his face you notice that the upper lid of the right eye droops, so as to conceal almost the whole of the iris. The little fellow is but eighteen months old, and is, as you see, remarkably strong and well developed for his age. The mother tells us that he is her fourth baby, and that her confinement was easy, labor lasting but one hour; a midwife was present, and no instruments were used; the head presented.

Immediately after the birth of the child it was noticed that the right upper eyelid drooped so as to cover the pupil. The mother states that the child has always been well, never having had any of the usual children's diseases. Inquiry into the family history shows no trace of hereditary disease. The father denies venereal infection. It is apparent that both parents are exceptionally healthy and robust people.

The patient resists so strongly that it is quite difficult for us to expose the iris in such a way that we can observe both eyes. Of course, without the assistance of the patient it is difficult to say that they are parallel, but they appear to be so. The pupils react quickly to light and accommodate to distance. It is apparent, therefore, that we have here only a paralysis of that branch of the third nerve supplying the levator palpebræ.

This is one of the congenital third-nerve paralyses, which, while they are not common, are still referred to in all standard text-books on nervous diseases and ophthalmology. It is peculiar in this case that the disease is unilateral, and that it involves but one branch of the superior division of the third nerve, that which passes to the levator, while the portion that supplies the superior rectus has entirely escaped. In all former cases of congenital ptosis that have here come under our observation, the disease has been bilateral, and there has usually been some involvement of other branches of the nerve, with consequent squint. Unilateral cases of this disorder, in which the eyelid would rise when the mouth was opened, have been reported by Helferich, Gunn, and Bernhardt. In the case reported by Gunn, it it was not only necessary to open the mouth, but also to carry it a little to the right.

So far as our present knowledge goes, we know nothing of the nature of this affection. It may be due to pressure upon the nerve during the birth of the child, or to some imperfection in the nervous apparatus, or perhaps to absence of the levator muscle. Whatever its cause, we must look to operation for its relief, and this consists in removal of a portion of the integument from the upper lid so as to shorten it so that the natural position of the eye is open, but the orbicularis is still able to close the eye. A later operation, and one quite popular, is to pass threads beneath the skin and bring them out above the eyebrow. In this way artificial bands of connective tissue are formed so that pulling the brow upward moves the lid.

TRAUMATIC PARALYSIS OF THE LEG.

The patient before you came into the room on a pair of crutches, with the left leg supported by a strap caught under the heel of the left shoe, and across the front of the thigh. He states that he is thirty years of age, and by occupation a railroad conductor. The family history is good, and prior to the accident the man's health has always been good. Venereal infection is denied.

The accident in which he was injured took place some four months ago. The car in which he was riding was thrown down an embankment some ten or fourteen feet, and he was precipitated with great violence toward the opposite side of the car. He does not know just how he struck. He thinks that he did not lose consciousnes, but was not able to move or speak. He was immediately given some whiskey, which made him cough, and this brought up some blood. After about an hour he seemed to gain a certain control of himself, and then began to experience very severe pain across the small of the back. This has continued until the present time, though it has been getting better, and it now rarely annoys him, except when he wrenches the back in some way. He remained in substantially the same condition until removed to a hospital, where it was necessary to draw his urine with a catheter, and clysters were used to move the bowels. It was noted at that time that his left leg was cold, and hot bottles were placed about it. These were too warm, and the leg was blistered without his knowledge, as sensation was completely abolished in the part. There has been some improvement in his general condition. The pain has to a great extent disappeared, and he is now able to go about on a pair of crutches, but since the accident he has never had the slightest voluntary use of the left leg. Two weeks after the injury he was able to pass water. His general health is now good.

Examination does not show the slightest deformity of the back, pelvis, or thighs. There is complete loss of sensation from a line drawn parallel with and about two inches below Poupart's ligament in front and two inches below the gluteal fold behind. Below this the senses of pain, touch, pressure, and temperature, are absolutely lost. The leg is blue and cold to the touch, and pits slightly on pressure. The patellar tendon-reflex is exaggerated in both legs, but there is no ankle-clonus. There were no ocular or oral symptoms, and motility and sensation of the upper extremities are normal. The reaction to the faradic current was slower, and required about twice the coil-distance to produce a muscular movement on the left side that was needed on the right. No galvanic reactions could be obtained in the left leg. In the right leg, C.C.C. 5.5, A.C.C. 7.5 milliampères, with about a normal faradic irritability.

As to the nature of this injury, we can only think of a hemorrhage into the spinal canal or into the cauda equina. There is one anomaly in the symptom-grouping that is found in the presence of the deep reflexes associated with trophic disturbance and the reaction of degeneration. This would almost seem to exclude the hemorrhage or other lesion of the cauda. If we assume that the lesion is in the cord, we are met with the fact that sensation and motion are both paralyzed, which would imply that the difficulty affected both sides of the cord. Perhaps in lesions of the lumbar cord there are sections in which the sensory and motor paths are associated on the same side of the cord. In any event, the retention of the deep reflexes in such a case cannot be explained by the ordinary views of the anatomy of the lower portion of the spinal cord.

NEURITIS FOLLOWING INFLUENZA; NEURASTHENIA; IRRITABLE PROSTATE.

This man is thirty years of age, has been married for six years, and has no children. Eleven years ago he contracted syphilis. He was perfectly well until the winter of 1890, when he had an attack of influenza that left him with a pain which is described by him as most severe at the lower portion of the sternum, radiating from this part downward and to the left, to a point some two inches below the left nipple. The pain was very severe at first, and as it was thought to have some connection with the specific trouble, he was given mercury with iodids. This relieved the pain, and he was free from it for about one year, after which it returned, and it has persisted with greater or less severity ever since. With the return of the pain specific treatment was again employed, but it failed to give relief. The pain varies somewhat in severity; at times it is very sharp, but he says that a dull ache is always present in the part. It is aggravated by deep breathing and by pressure.

The general condition of the patient seems to be fair though he is of markedly nervous temperament. His bowels are regular, appetite is fair, and sleep good. As he stands with eyes closed and feet together, there is a marked tremor of the upper eyelids. The deep reflexes are a trifle exaggerated, both of which symptoms are commonly present in neurasthenia. There are no other general nervous symptoms. On the anterior aspect of the left side of the chest there is an area of anesthesia corresponding with the distribution of the seventh and eighth intercostal nerves. Carefully palpating the intercostal space with the rubber tip of a lead-pencil reveals two tender points in the course of the seventh nerve, and one in the course of the eighth. We think from these symptoms that we are justified in making a diagnosis of intercostal neuralgia, probably dependent upon neuritis which came on at the time he had the influenza, and which is in no way connected with the specific trouble. It is well to remember that while this pain may be due to neuritis, it is found in a marked neurasthenic, one of a class of patients especially liable to pains without organic changes in the nerves.

In addition to these other symptoms, the man complains of occasional pain in the head of the penis, radiating to the root of the organ. The urine, which is passed freely, contains a few clap-threads (Ripper-fäden). There is no disturbance in micturition. Exploration with olive-tipped sounds does not show any narrowing of the canal, but sensitive points are found at the neck of the bladder, and one or two inches in front of it. Rectal exploration shows the prostate to be of normal size, but very sensitive. The absence of organic changes in the urethra and prostate leads us to regard these conditions as a local expression of the general neurasthenic state. While we are confident that with a healthier nervous system there would have been no local disturbance at the neck of the bladder, we shall not neglect the latter in our treatment, but will use a mild injection of nitrate of silver (2 per cent.) in the deep urethra. We shall expect this treatment to favorably influence the local symptoms. The constant galvanic current will be applied to the intercostal nerves with the positive pole over the terminations of the nerves and the negative between the shoulder-blades. From eight to twelve milliampères will be used for about ten minutes each day. The current will be turned on and off slowly, and all interruptions avoided. Strychnin will be employed internally in doses sufficient to produce its full physiologic effect.

SPASM OF MUSCLES OF THE FOREARM, WITH TROPHIC CHANGES; TREMOR OF THE TONGUE.

This patient is thirty-four years of age, a machinist by occupation, married for the past eight years, and has four healthy children. Fourteen years ago he contracted syphilis—at least he had a chancre which was followed by a suppurating bubo. He does not think that he had an eruption on the skin, but states that he had falling out of the hair some weeks after the primary sore. From that time until six months ago he had perfect health, was then working at his trade, and was employed eighteen hours a day, when he noticed a twitching in the throat and some impairment of speech. His physician regarded these symptoms as being due to bulbar paralysis of specific origin, and gave him potassium iodid, under which treatment the symptoms improved, though he did not entirely recover. Some two months ago he was seized with violent contractions of the muscles of the left forearm. These continued to grow rapidly worse until the present time. They were not attended by pain, and the patient has been able to continue at his work until within a few days, since which time a severe inflammation of the metacarpo-phalangeal articulations of the first and second fingers has developed. The constant move-

ment of these joints by the spasms in the muscles causes much suffering, but aside from this there has been no pain.

His present condition is good, his appetite excellent, the bowels regular, and the urinary system normal. There is no incoördination nor any subjective sense of vertigo. He stands easily with eyes closed; when in this position the upper lids are tremulous. The deep reflexes are slightly exaggerated. The pupillary reactions, fundus oculi, and fields of vision are normal. Hearing is equally good upon both sides. There is no pain in the head, and sleep has been good throughout the whole course of the disease. At no time has there been elevation of temperature. The tactile, common, and thermic senses are normal over the entire surface of the body. A careful comparison of the forearms in this respect does not show the slightest difference. The contractions are confined to the left forearm, and while there is marked loss of strength, there is still some movement in the affected fingers. It seems as though the little and ring fingers were capable of more extended movement than the others. The skin of the fingers has a decidedly shiny appearance due to trophic changes. There is no apparent diminution in the size of the muscles, though there is a loss of strength on voluntary movement. Owing to the constant agitation the electric reactions of the forearm cannot be obtained.

It is apparent that we have an irritative lesion in this case, but its exact location is a matter of some question. A cortical lesion is suggested by the limited extent of the lesion, but against this view are the trophic disturbances and the absence of all symptoms of meningeal irritation. The limited extent of the lesion militates against the view that it is located at the base, along the great conducting paths in the peduncles, pons, and medulla. On the other hand, the trophic changes are suggestive of spinal or peripheral nerve-disturbance. In view of the singular grouping of symptoms, we feel that it would be hazardous to venture a local diagnosis at this time. The most that we can say is, that there is an irritative lesion somewhere along the motor tract to the left forearm, and that it is probably of specific origin. We shall recommend that he be put on very large doses of potassium iodid, from 100 to 200 grains daily, and that he report at the end of a week.

CLINICAL MEMORANDA.

TETANUS COMPLICATING VACCINIA.

By S. W. S. TOMS, Ph.G, M.D.,
of Bellport, L. I;
late House Surgeon, Buffalo General Hospital.

On November 6, 1893, I was requested to vaccinate M. D. W., a female white child, five years and five months of age, of American birth and parentage, and apparently healthy. The father is living, and healthy. The mother has two children, and has had one five months' miscarriage. She is of a strumous diathesis, and has had suppurative cervical adenitis. A second sister, aged about sixteen years, is living and in good health. The mother had scarcely made a tedious recovery from a five months' spontaneous abortion, when she again became pregnant. She was in a poor state of health throughout the entire period of gestation, having been subject to some severe trials and afflictions and emotional shocks. The child consequently started life handicapped, developed a neurotic temperament, and was the subject of a strumous diathesis, weak vitality, and poor nutritive functions, slight ailments always profoundly affecting her. Two years ago she had measles, followed by mumps, and although both attacks were light she had a strumous keratitis developed upon a preëxisting conjunctivitis. She suffered from exacerbations of chronic nasal catarrh and dyspeptic attacks. She was much pampered by her parents, who over-dressed her and indulged her in every whim. When in good health she was bright and vivacious, although a delicate child. On November 6, 1893, I vaccinated the child with a fresh ivory-point of bovine virus, using alcohol and a clean towel in preparation of the field of inoculation. The tenotome, with which I scarified the skin of the left arm at the insertion of the deltoid muscle, fifty millimeters square, was sterilized. The slightest scarification possible were made, and the point, moistened with water, from a driven well, was gently rubbed in, covered by a small piece of Lister's green protective and bandaged. This very slight operation produced great pallor, and the child almost fainted. I mention these minute details for reasons obvious that will appear.

I directed the mother not to disturb the bandage for several days; to use a simple dressing of vaselin, and to keep the ulcer free from accumulating pus by weak carbolized washings; and should there be any severe cellulitis, to bathe the inflamed area with aqua hamamelis. I cautioned against allowing the vaselin used to be employed for any other domestic purpose, and to use nothing but *clean* linen or muslin rags; and should anything require my professional attention to advise me accordingly.

I was informed on my second visit, November 24th, just eighteen days from the date of vaccination (when I was requested to call because the sore was not doing well), that my directions had been carried out. The vaselin had been taken from a partly used bottle into which those who had made use of it dipped their fingers. A quantity for this special purpose had been set aside on an individual butter-dish, uncovered, on a shelf in a cupboard. I found the child slightly indisposed, with a temperature of about 100.5°, with the tongue slightly coated; she was not inclined to eat, and had sluggish bowels. The arm was not swollen or discolored to any extent. The ulcer was about the size of a silver fifty-cent piece, deep, and containing a quantity of sanious pus of a very fetid odor. I examined the axilla, but no nodes were perceptible, nor did the child complain of tenderness at this point or around the sore. I inquired into the history since vaccination, and was informed that four days after I inoculated the arm it was inspected. Slight redness existed at the site of scarification, and there was a vesicle in process of formation. The surrounding parts were bathed and rubbed with witch-hazel water, and the protective and bandage were reapplied.

During the latter part of the second week the slough was complete. At no time had there been much disturbance; the cellulitis was insignificant, and the child was out playing every day. For a few days previous to my second visit there appeared an offensive odor, and

the pus was more abundant, although the child did not give evidence of any aggravation of the local trouble. The ulcer was full of pus; it had not been dressed since the evening before, awaiting my visit. There was nothing in its appearance to arouse suspicion. The ulcer was deep and the granulations were unhealthy, because of the indolent character they presented, and induration existed around the edges for a distance of about 1 cm. It had been cleansed by using a sponge and 4 c.c. of carbolic acid to 500 c.c. of warm water. The vaselin was said to have irritated the part where it had been applied to the edges to prevent the dressings adhering, and had been discontinued for a week or more. The witch-hazel water was used for bathing the parts, and the wound was dressed twice daily. I prescribed calomel in 0.015 doses every hour, until a stool should take place, to be followed by oleum ricini or Rochelle salts; to employ 4 c.c. of carbolic acid to 250 c.c. of boiled water instead of 500 c.c., as had been used; to discard the use of the sponge and employ a syringe or irrigator, and to moisten the dressings in the same solution, and to use balsam of Peru after the ulcer had been thoroughly cleansed. The vaselin was not used further.

I was informed that under this treatment immediate improvement was perceptible. The odor and the pus did not reappear. The dressing only required changing once daily. The bowels responded, appetite returned, and the child felt reasonably well. The size of the ulcer diminished, and what little induration existed around the margin disappeared entirely, and the granulations immediately assumed a healthy character.

On November 30th, the father took the child out for a walk, and when near the bay, a stiff breeze blowing at the time, she complained of a sharp pain in her throat on the right side, just posterior to the angle of the jaw. When she returned home the mouth was examined, and a number of small aphthous ulcerations on the margins of the tongue and lips were noticed. I was requested to call and see her. I found the child with a slight stomatitis and the aphthous patches mentioned. The tongue had a dark-gray coating. The pulse was 96, and the temperature 100.5°. The bowels were constipated, and the appetite fair up to that day. I wished to examine the throat, and on depressing the base of the tongue with the handle of a spoon (the child could not separate the jaws more than 75 mm.), she would close her mouth and bite on the handle, holding it for a few seconds quite firmly. I made three attempts with a like result, and abandoned further efforts, as the child was peevish. This trismus was characteristic; but as it often happens in such examinations with children, I attached no importance to the occurrence.

I prescribed a simple antiseptic astringent mouth-wash, also advising the extraction of a number of ragged decayed teeth, as there was occasionally some pain in the throat radiating from the angles of the jaws, and the left cheek and upper lip were slightly swollen. Providing she had fever, she was to be sponged with tepid water and alcohol until remission occurred. This was done once or twice, free diaphoresis following. On my visit next morning I found the patient about the same, with possibly more trouble in the throat, of which complaint was made on swallowing. The girl had not been taken to a dentist. There had been periods of depression and restlessness, and the child had taken only liquid nourishment and wished to drink frequently, which was allowed as much to cleanse the mouth as on general principles, as it was almost impossible for the parents to get her to use the mouth-wash to any effect. She talked freely, and most of the time seemed bright, but was apprehensive and wanted to be held in the lap. Occasionally, after sleeping, she would have slight strangling attacks from the accumulated mucus in the throat, which seemed to excite trismus, for she had difficulty in expelling it. Biniodid of mercury, 0.00065, was given every hour for "sore-throat"; also a mixture containing sodii bromidum and chloral, 0.24 of each to a dose.

I saw her again early on December 2d, still finding the symptoms about as before, together with some rigidity in the muscles of neck, and pains complained of in the back. The latter I attributed to her position, as she was almost constantly held in the lap. Although the child's general condition did not improve, she was less restless. The bowels were constipated, and calomel in 0.015 doses hourly was ordered until a stool was induced. She also had retention or suppression of urine, only urinating twice in twenty-four hours and indiminished quantity. The arm was examined each day and appeared healthy, not sore or inflamed; the temperature and pulse were normal. In the evening I was hurriedly summoned, as the child "had spit some blood" in one of her strangling or coughing attempts to expel the accumulated mucus from the throat. This was no doubt due to an injury to the tongue from trismus. The aphthæ seemed to be getting worse, and all attempts at using the mouth-wash with a swab excited trismus. In fact, the muscles of the jaws seemed to be in slight tonic spasm, as the girl was unable to separate her jaws more than from 60 mm. to 70 mm.; yet she conversed freely and drank her broth and milk up to this time quite readily. At midnight I was again called and informed that she had had a convulsion—"became stiff, did not breathe, and bent backward." This lasted "about a half-minute." When I arrived at the house she was resting quietly. She had not had any of the antispasmodic mixture since the previous afternoon. Although she sat up in bed, drank some broth and talked, and afterward relapsed into a quiet sleep, she could not be induced to take the medicine or use the mouth-wash. I remained until 2.30 A.M., leaving a bottle of chloroform to be used in case of further convulsions. What I had been apprehending for thirty-six hours I now became convinced was true, and I determined in the morning to suggest counsel, which I did; when I was called at 8.30 A.M., with the intelligence that she had had three more convulsions, but of slighter character—the anesthetic being promptly brought into use.

At noon of December 4th I met in consultation Dr. A. H. Terry, of Patchogue. During our examination the child had a typical paroxysm with opisthotonos, and deep anesthesia failed to separate her jaws. The grave prognosis I gave early in the day was confirmed by my confrère. The plan of treatment agreed upon was bromid and chloral per rectum, nutritive enemata, ice-bags to the spine, and chloroform when necessary to control the spasms. The paroxysms were clonic. The girl lapsed into coma from the time the anesthetic was administered; at the time of which she also received a

nutritive enema with the antispasmodic mixture, combined with tr. opii deod., gtt. x, and every three hours subsequently. While under the influence of these she was perfectly free from convulsions, even her jaw relaxing to its full extent, allowing the nurse to swab out the buccal cavity, which was not possible before.

In the morning I had detected cooing and mucous râles at the left base posteriorly. This unfavorable sign rapidly advanced and soon appeared as well in the right lung, and although she subsequently had only six more very slight convulsions she died from edema of the lungs on the next morning, December 5th, at 10.45. She had eleven distinct and characteristic convulsions, four of which were moderately severe, but lasting less than thirty seconds.

Although the course of the disease was short, its essential characteristics answered perfectly to the description given by Watson:

"During the fits of exacerbation the aspect of the sufferer is often frightful. The forehead is corrugated and the brow is knit, the orbicularis muscle of the eye rigid, the eyeball motionless and staring, the nostril spread, the corners of the mouth drawn back, the set teeth exposed, and all the features fixed in a ghastly grin—the true *risus sardonicus*. The tongue is apt to get between the teeth and be severely bitten. All the contractions are attended with intense pain."[1]

At the time of death the ulcer on the arm was not larger than a silver quarter of a dollar, was superficial, without tenderness or discoloration of the surrounding skin, or induration. Pus was slight, granulations were healthy; there was no cellulitis in the arm, nor were the axillary glands enlarged. Several hours before death the face became "bloated," the eyelids and lips much swollen, the jaw relaxing and the mouth open, while the purulent discharge drained along the dependent track of the buccal cavity and angle of the mouth quite profusely. The face soon after death rapidly assumed the natural features; the emphysema (?) entirely disappeared. Cutaneous discoloration from blood-stasis in the superficial circulation was marked in the dependent portions of the body, and rigor mortis was well advanced in less than one hour after death.

From the fact that this fatal case of tetanus has created a grave suspicion in the minds of a large number of people generally[2] and a deep prejudice in the locality against vaccination, I undertook to collect statistics from various sources. I wrote to the managers of the vaccine farm—one of the largest, most reputable, and scientifically conducted establishments in the world; and one in which thousands of the best physicians have unqualified confidence, besides being, perhaps, the largest producer of vaccine on the continent—and was informed that they had never had a case reported to them from the millions of points they had sold, nor had they heard of a case of tetanus from vaccination.

I also wrote to Dr. Cyrus Edson, Health Commissioner of the city of New York, and Surgeon-General George M. Sternberg, U. S. A. Replies from these gentlemen and from Dr. J. S. Billings, of the Army Medical Library, are reproduced. Besides these I have to state that I am greatly indebted to the courtesy of Dr. Judson C. Smith, of the Pathological Laboratory of the New York Post-Graduate Medical School and Hospital, who endeavored to make cultures from some of the pus and part of the tissue taken at time of death from the vaccination ulcer on the arm, *with negative results*. Efforts were made to obtain cultures from the point used for inoculation, and this also without success.[1]

[1] Prac. of Phys., Lect. xxxii.

[2] Several distorted articles appeared in the New York City papers, particularly in the New York *Sun* of December 9, 1893—only another evidence of the utter inability of the lay mind to correctly state facts or describe a scientific subject devoid of sensationalism. Also, an article appearing in the Suffolk Co. (N. Y.) *Argus* of January 6, 1894, emanating from a homeopathic physician of a neighboring town, stating that death was "lockjaw caused by vaccination," and denouncing in unmeasured terms vaccination and the statute that makes it compulsory.

[1] D. Cyrus Edson, of New York, wrote: "During my services in this department I have supervised the performance of over one million vaccinations; among all these cases not a single instance of tetanus has occurred. I believe that the disease is endemic in the eastern part of Long Island, and possibly as near us as Bellport. I should consider an abrasion of any kind in the locality I have named a dangerous thing. For this reason it is very unjust to blame vaccination for the circumstance."

Dr. George M. Sternberg, Surgeon-General, wrote as follows: "I do not know of any case of tetanus having occurred as a complication of vaccination, but I will refer to Dr. Billings, who has charge of the Army Medical Library, requesting him to have the literature of the subject looked up. As your case occurred four weeks after the vaccination, I agree with you in believing that it was a secondary infection, for which you were in no way responsible."

Dr. J. S. Billings, Surgeon U. S. A., wrote as follows: "I enclose herewith a memorandum of six cases of tetanus following vaccination, which are all I find recorded under that heading. You will see that they were all secondary infections:

"CASE I.—Dr. W. T. C. Bates, *Transactions of South Carolina Medical Association*, 1882, page 105. Mulatto boy, aged five years; vaccinated February 9, 1882, with humanized virus. Tetanic symptoms supervened March 8th. No other cause than vaccination found. Boy lived fifteen days.

"CASE II.—Dr. R. Carcia Rijo, *Cronica Medico-Quirurgica de la Habana*, 1886, vol. ii, page 388. White child, two years old; vaccinated in April, 1886; characteristic tetanus appeared in latter part of May. No lesion beyond vaccination found. Death followed on fourth day.

"CASE III.—Dr. George Ross, *The Southern Clinic*, 1878 79, vol. i, page 468. Boy, three and one-half years old; vaccinated, tetanus supervening three weeks afterward, with death on the third day. No other lesion beyond vaccination.

"CASE IV.—Dr Theodore Dimon, *St. Louis Courier of Medicine*, 1882, vol. vii, page 310. Boy, nine years old, vaccinated January 6, 1882; bovine virus. Tetanus set in January 27th; no cause discovered except from vaccination, which was followed by an irregular-shaped ulcer Boy died on tenth day.

"CASE V.—Dr. Joseph B. Cottman, *New Orleans Medical and Surgical Journal*, 1854–55, vol. ii, page 783. Negress affected with tetanus following vaccination; period of time not stated. Recovery in two weeks by the use of large doses of opium.

"CASE VI.—Dr. H. J. Berkeley, *Maryland Medical Journal*, 1882, vol. ix, page 244. Healthy man, forty years old, vaccinated in middle of January, 1882. February 7th, tetanus set in; death followed February 13th. No lesion was discovered except at the point of vaccination; on the latter there was a deep ulcer, which had an inflamed and indurated border."

Dr. George M. Oxford, of Ridgewood, N. J., wrote me: "I have had under treatment, since November 29th, a case of idiopathic tetanus; it came on suddenly, without any vaccination or injury as far as can be learned. The symptoms were very severe

The fact that the child had an aphthous sore mouth, with a purulent discharge from the buccal cavity or throat, together with the open wound on the arm, leaves open a question of just how secondary infection may have occurred. True it is the sore mouth was coincident and coexistent with the first symptoms of the disease. Watson[1] cites cases of tetanus from salivation. Moreover, beside this case stand the hosts of so-called idiopathic cases. Although no attempt is made to believe this case might have been such in view of the presence of an open wound on the arm and eroded mucous membranes of the mouth and throat, yet the possibility of such being a coincidence might not be altogether disregarded.

From the period of time elapsing from the date of vaccination to the developing of the tetanus, it is certain that this does not correspond to the accepted view of the period of incubation.[2]

In conclusion, the possible source of infection of *the ulcer* might have been from (1) vaselin (which might have been infected from previous use); (2) sponge (which might have been dirty); (3) unsterilized dressings; also from the solution of continuity of the mucous membranes of the mouth and throat.

Against the theory that it was due to vaccination is

1. The existence of "sore mouth," which is possible as offering a nidus for infection.

2. The date of onset not corresponding to the generally accepted period of incubation; and absence of bacilli of tetanus in the pus and tissue from the wound.

3. The fact that the disease manifested such a mild course, and that the fatal issue was depending upon an intercurrent complication. Had not this unfortunate circumstance occurred, and had the child possessed ordinary vitality, it is but reasonable to assume that she would have recovered.

A point that is a matter of regret to the writer is that there was no attempt made to obtain cultures from the purulent discharge from the mouth.

at first, with marked trismus. Now there is more remission and better sleep, but renewal of lighter attacks from reflex irritation, such as noises, etc. I write you this to show that other causes than vaccination may account for your case. My patient is twelve years old."

[Dr. Oxford evidently had seen one of the New York papers with the account of my case, and voluntarily wrote me the foregoing letter. I am not personally acquainted with him. The Doctor writes me under date of January 22, 1894, that his patient is still under treatment, and that his condition is almost unchanged.]

[1] Watson's Prac. of Physic, Lect. xxxiii.

[2] "Within two weeks" (Osler, page 162). "Most frequently makes its appearance at end of first week" (Amer. Text-book of Surgery, page 67). Although Senn Principles of Surgery, page 392) says: "The period of incubation appears to be extremely variable."

LEUKOPATHIA UNGUIUM.

By F. J. STOUT, M.D.,
OF PHILADELPHIA, PA.;
INSTRUCTOR IN DERMATOLOGY IN THE PHILADELPHIA POLYCLINIC.

THIS term (derived from λευκός, white, and πάθος, disease) has been given to that condition in which white spots appear upon the nails. A very striking example of this peculiarity was exhibited in the case of A. C., a mulatto, who presented himself in July, 1893, at Dr. Van Harlingen's clinic at the Philadelphia Polyclinic for treatment. The patient is a waiter by occupation, and twenty-one years of age; he has scrofulous glands on the left side of his neck, and is suffering with gastritis; his mother died of tuberculosis; his father is still living. He had always enjoyed good health until last April, when he had an attack of influenza. He is an individual of medium size, and fairly intelligent; at present he is somewhat nervous and weak. The nails of his fingers, and some of those of the toes, present quite a peculiar appearance, being marked with wavy white lines and white spots of a milky color. It will be necessary to describe the appearance of the nails on the individual fingers and toes separately, as they differ somewhat. The nails of the index, middle, and ring fingers of the right hand (see illustration) are marked with a wavy, transverse, white line or lines, more or less perfect, extending from one margin of the nail to the other; between the lines on the index and middle fingers there exist interspaces, which

are normal in color and each about one-sixteenth of an inch in width; the nails of the thumb and little finger are marked each with three separate white spots. On the left hand a similar condition is also observed to exist; each of the nails of the middle and ring finger of this hand exhibits a transverse white band, more or less irregular in contour, extending from one margin of the nail to the other; the narrow strip of intervening normal color between the bands, referred to as existing on the index and middle fingers of the right hand, is, however, lacking on these finger-nails. The band on the middle finger occupies about one-half of the length of the nail; the nail of the thumb is marked with a distinct large white spot on its margin; the nail of the little finger presents a white spot on its surface near the center, and is white along its margin. The nail on the index finger has three transverse bands, which do not extend entirely across the nail-surface, and between these there exists an interspace of about one-eighth inch, which is normal in color. The rest of the nail-substance of all of the fingers appears normal in every respect, and presents a healthy and glossy appearance.

Some of the nails on the toes are similarly marked. On the nails of the right foot white bands are visible, which extend partially across the nail-surface, and also exist at the margin of the nails of the great toe, the second, third, fourth, and fifth toes. On the left foot the margins of the nail of the great and second toes are marked respectively with a similar white line. With this exception, the nails of the toes of both feet do not show any abnormality whatever, and are perfectly healthy in other respects. The hair of the individual does not show any discoloration, but is quite black in color.

According to the patient's statement, these lines and white spots have been present ever since he can remember, and have never disappeared at any time, and no other member of his family on either side has been similarly affected; it would appear from the history of the case that the condition is probably congenital.

The appearances presented by the finger-nails in this man are similar to those existing in a case described by Morison, of Baltimore,[1] occurring in a young lady, twenty years of age, which made their appearance without ascertainable cause, and disappeared after a few months; the nails of the toes, however, were not affected, differing, therefore, in these respects from the case under consideration. Dr. Morris Longstreth, of Philadelphia, in a paper entitled "On Changes in the Nails in Fever, and Especially in Relapsing Fever," describes the appearance of white bands on his own finger-nails after an attack of relapsing fever, which occurred at the time of each relapse of the fever. Crocker (*Diseases of the Skin*) quotes a case recorded by Bielschowsky[2] of a man with peripheral neuritis, in which white spots appeared at the lower part of the finger-nails, rapidly grew, and in three weeks coalesced into a band extending across each nail, a millimeter wide. The toes were not affected. Cases are also on record by Giovannini and Unna[3] (quoted by Crocker) in which the nails on the hands of male individuals were completely white. In Giovannini's case the affection followed an attack of typhoid fever in an individual twelve years old; the hair retained its original color. In Unna's case the condition was probably congenital, and the hair presented a partial appearance of the condition known as ringed hair. Dr. Langdon Down[1] records the presence on the fingers and toes of a gentleman, of two distinct sets of white lines extending transversely over the nails, which made their appearance after he had experienced two attacks of poor health from severe overwork; in this case marked prostration, intermittent action of the heart, and ulceration of one cornea existed; the lines on the nails corresponded with the time of the occurrence of the two attacks. Dr. Herman Lawrence describes[2] a case of leukopathia unguium, characterized by the presence of white bands, in an apparently healthy middle-aged man, which he regards as congenital. The nails on the fingers of this patient's child, a boy five years old, presented a similar appearance, though not so distinctly marked. Dr. Lawrence expressed the opinion that the nails of the child would, in the course of time, show the identical banded condition existing in the father's case.

Careful microscopic examination of nail-substance marked as in the case here described, shows the white bands to consist of air-spaces in the nail substance, similar to those found in gray hairs; we are, however, unacquainted with their mode of origin. White spots, which occur occasionally on entirely healthy nails, point to passing changes in the site of formation of the nails (Hyrtl). Among convalescents from malignant fevers the nails have been noticed to become white. Whiteness of the nails of a chalky hue has been observed in paralytic patients. Sometimes the appearance is evidently partially dependent on trophic changes, as in the cases of Longstreth and Down. According to Hutchinson, white spots may be due to picking back of the nail-fold, and frequently coëxist with similar white spots on the teeth. Geber is of the opinion that they are produced by mechanical means that interfere with the complete cornification of the nail-cells. To these white spots on the nails the ancients gave the name of flores unguium, and in Fallopius' time they were called mendacia ("lies"), and are still vulgarly known as "flowers," or "lies," and as "gift-spots." I am indebted to Dr. E. L. Billstein for the accompanying illustration.

A Royal Physician.—A number of months ago we took occasion to call attention to the noble work of Duke Karl Theodor of Bavaria. It transpires that another member of the same house, Prince Louis Ferdinand, has likewise engaged in the practice of medicine. The Prince is the cousin of Duke Karl Theodor, nephew of the Prince Regent of Bavaria, husband of the Infanta Maria de la Paz of Spain, and is twenty-three years old. He has recently published a monograph detailing the results of a study of the etiology and pathology of pleurisy, based upon clinical, bacteriologic, and therapeutic observations in twenty-three cases.

HOSPITAL NOTE.

A CASE OF RUPTURE OF THE LUNG, UNASSOCIATED WITH FRACTURE OF THE RIBS, WITH EARLY SUBSEQUENT RECOVERY.

Emergency Hospital, Washington, D. C.

SERVICE OF JAS. KERR, M.D., M.CH.,
ATTENDING SURGEON.

Reported by W. L. PYLE, A.M., M.D., Resident Physician.

THE mechanism of this rare and fatal form of injury has been very aptly described by M. Gosselin. It is due to a sudden pressure exerted on the thoracic wall at the moment of full inspiration, there being a spasm of the glottis or obstruction of the larynx; in consequence of which the lung bursts. An extravasation of air occurs, resulting in the development of emphysema, pneumothorax, etc. Subsequently pleurisy, pneumonia, or even pus in the pleural cavity often results. Hemoptysis is a possible, but not a marked symptom. The mechanism is identical with that of the bursting of an inflated paper bag when struck by the hand.

M. Gosselin reports two cases terminating in recovery. Dr. John Ashhurst, Jr., reports having seen three cases, all of which terminated fatally before the fifth day; he has collected the histories of thirty-nine cases, of which twelve recovered. Dr. Otis has collected reports of twenty-five cases of this form of injury from military practice exclusively. These were generally caused by a blow on the chest, by a piece of shell, or other like missile. Among the twenty-five cases there were eleven recoveries. As Dr. Ashhurst very justly remarks, this injury appears more fatal in civil than in military life.

That so severe a form of injury should show such a rapid and continuous recovery as in the case here cited is without a doubt extraordinary, and would seem to make it worthy of report.

Lewis W., ten years old, white, born in Maryland, and living now in the District of Columbia; was brought in by the Emergency Hospital ambulance on the afternoon of November the 10th, with a history of having been run over by a hose-cart of the District Fire Department. The boy was in a state of extreme shock, having a weak, almost imperceptible pulse; his respirations were shallow and rapid, and his temperature subnormal. There were no signs of external injury about his thoracic cavity, and no fracture of the ribs could be detected, although carefully searched for; there was marked emphysema; the neck and side of the face were enormously swollen with the extravasated air; the tissues of the left arm were greatly infiltrated with air, which enabled us to elicit the familiar crepitus of such infiltration when an attempt at the determination of the radial pulse was made. Consciousness was never lost. There were several injuries to the face and scalp; and there was hemorrhage from the nose and mouth, which was attributed to the fact that the patient had fallen on his face, striking both nose and lip. This was confirmed subsequently by the absence of any evidences of hemoptysis during the whole period of convalescence. The saliva was not even blood-streaked; therefore it can be said with verity that there was no hemoptysis.

The first indication in this, and in all similar chest-injuries, is to limit the amount of thoracic expansion. To effect this, the chest was securely strapped with overlapping bands of adhesive plaster, extending nearly around its whole circumference, and a muslin binder was applied. Hypodermatic injections of strychnin and whiskey were resorted to, and hot-water bottles applied, the patient being wrapped in blankets. It was soon found that the respirations were easier, and the pain less marked when the patient was propped up in bed by several pillows, than in the dorsal position. To further control respiration, morphin sulfate in doses of one-sixteenth grain was given at sufficient intervals to keep the rate below 20.

Shortly after admission the patient reacted to the stimulating treatment, his pulse became stronger, and all evidences of threatened collapse disappeared. He rested well the first night and complained of no pain, then or subsequently. The improvement was continuous. The temperature remained normal until the evening of the fifth day, when it rose to 102.2°, and again on the evening of the sixth to 102.3°. This rise was apparently without significance, as the patient at no time seemed disturbed by it. On the eighth day the temperature again reached the norm and has since remained there.

The advisability of thoracic puncture and superficial scarification of the infiltrated tissue to relieve the emphysema was considered; but realizing that such emphysema was not in itself dangerous and that the patient's condition constantly improved under treatment, these procedures were not employed. The wisdom of this decision was demonstrated by the continued absorption of the air and diminution of the emphysema until the ninth day, when it was entirely absent from the tissues. A slight pneumothorax, however, remained. On the ninth day the chest was again carefully examined for evidences of a fracture, but the result of this second examination was again negative; leaving no doubt but that the case was one of rupture without fracture. There developed a slight, dry cough on the fifth day, which, however, soon subsided without any further treatment. The diet was exclusively of milk for a week, when light diet was substituted. The bowels were kept open daily by salines and enemata.

The boy is apparently well now, suffers no inconvenience, and has left the hospital, safe from danger and apparently free from any pulmonary embarrassment. He uses well-developed diaphragmatic breathing which is fully sufficient.

MEDICAL PROGRESS.

A New Method of Examining the Kidney, especially for Stone—At a recent meeting of the Philadelphia County Medical Society, DR. CHARLES P. NOBLE reported the case of a woman, thirty-seven years old, in which the kidney, its pelvis, and perhaps an inch of the ureter, were examined through an exploratory incision in the loin. During a period of six years there had been three attacks of hematuria, accompanied with "renal colic," good-sized stones being passed on two occasions, and the last coming from the left kidney. There had been, besides, milder attacks of paroxysmal pain referred to the right inguinal region, the pain being perhaps most acute just above the greater trochanter of the right femur.

These attacks had become of daily occurrence, and

were brought on when the woman was on her feet. She was usually, though not always, comfortable when in bed, but the pains came on shortly after attempts at walking. The sexual organs were normal, with the exception of a trifling tear in the perineum. The urine was examined many times, and had a very uniform composition. Its specific gravity varied between 1013 and 1020, and the reaction was acid; it contained pus, vesical and ureteral epithelium, but none from the pelvis of the kidney. The urine from each kidney was examined separately, being obtained by means of the ureteral catheter, and was found much the same, the pathologic elements being somewhat more numerous on the right side. The urine from the left kidney always flowed through the ureteral catheter freely and regularly; that from the right kidney did not. Upon two occasions the ureteral catheter remained in position upon the right side upward of twenty minutes, and not more than one or two drops of urine flowed out. Upon another occasion, after waiting thirty minutes with the same result, suddenly 120 minims poured out.

The conclusion was reached that there was a stone in the pelvis of the right kidney. Several attempts were made to pass a ureteral sound along the ureter toward the kidney, but it was not possible to make the sound reach above the brim of the pelvis. It was therefore proposed that an incision be made in the loin for the purpose of examining the kidney and the upper portion of the ureter from above.

Accordingly the usual incision in the loin was made down to and through the peri-renal fat, exposing the lower end of the kidney. With the index finger the kidney was then separated from its connective-tissue attachments and gradually drawn down into and out through the wound, so that it was entirely outside. It was now a very simple matter to explore the kidney by thumb-and-finger pressure, and to make certain that it was in a normal condition. It was equally easy to examine the pelvis of the kidney and to determine that this contained no stone. Perhaps one inch of the ureter also was within reach.

As nothing abnormal could be felt, the kidney was replaced within the abdomen and the incision was sutured in the usual way—buried silkworm-gut sutures being placed in the muscular layer, and superficial silkworm-gut sutures in the skin. No unfavorable reaction followed this operation, and so far as the operation itself was concerned the patient made an uninterrupted recovery. Unfortunately the operation produced no effect whatever on the symptoms.

The opinion is expressed that it should be a simple and safe matter in the hands of a skilful surgeon, who has had some experience in kidney-work, to remove through an incision in the loin all non-suppurating kidneys having approximately the normal size, for the purpose of a careful examination. The procedure is certainly not one of much gravity, and when done under the conditions laid down should have no mortality. Tentatively the adoption of this method of exploring the kidney is recommended whenever the symptoms point to the presence of stone in the kidney or its pelvis, and when these symptoms are of sufficient gravity to invalid the patient.

Upon theoretic grounds this procedure would not be applicable in cases of abscess of the kidney. Under these conditions the kidney would supposedly be fixed and not easily separated from its connective-tissue bed. Moreover, it would be enlarged, and in addition to this there would be the risk of rupturing the pus-sac, perhaps into the peritoneal cavity.

Akromegaly.—At a recent meeting of the Manchester Medical Society, Dreschfeld (*British Medical Journal*, No. 1716, p. 1107) presented a man, thirty years old, who five years before began to display symptoms of akromegaly. The bones of the face and skull were enlarged, especially the lower jaw; the hands and feet showed the characteristic thickening and enlargement, and the bones of the forearm and the clavicles likewise to some extent. There was atrophy of both optic discs, with complete blindness of one eye and diminished vision of the other, without hemianopsia. The thyroid gland could not be felt, but on either side was a well-defined swelling, dipping down into the thorax, and being apparently connected with a mass there which gave rise to dulness on percussion over the upper portion of the sternum. The voice was hoarse and the epiglottis was thickened, but there was no paralysis of the vocal bands. The subjective symptoms consisted of occasional pains in the head. There was also marked sexual weakness. The patient came under observation on account of the excessive dyspnea, which soon yielded to arsenic, with distinct diminution in the size of the tumor-masses in the neck, so that the man was able to resume his avocation. In a discussion of the pathology it was pointed out that neither the persistence of the thymus nor the enlargement of the pituitary body, which must be considered only as one of the symptoms of the disease, can be looked upon as the cause of the disease, which appears to be rather neurotrophic in nature.

Membranous Enteritis in a Young Child.—Thomson (*Archives of Pediatrics*, vol. xii, No. 1, p. 36) has reported the case of a child, two years and four months old, that came under observation on account of being out of sorts and passing pieces of membrane in the stools. The child was pale, but otherwise appeared to be perfectly healthy. Some three months later a second attack of similar character occurred. Both were attended with restlessness at night, crying out, grinding of the teeth, and throwing off of the bedclothes. There was a good deal of tenesmus. The administration of laxatives was followed by the appearance of blood in the stools. The membrane presented the characters of that met in croup. Some of the thicker pieces were distinctly composed of two layers. At times the membrane was passed as an entire tube enclosing the formed feces. Under the microscope it presented a glassy-looking matrix, in which were imbedded at pretty regular intervals numerous epithelial cells in process of fatty degeneration, besides colorless blood-corpuscles and innumerable microörganisms of various forms and sizes. On chemic analysis the membrane was found to be composed mainly of fibrin. In both attacks a mixture containing nux vomica, sodium bicarbonate, and rhubarb was given, and also a few doses of gray powder and rhubarb. This treatment seemed to exert a favorable influence, being followed in a few days by diminu-

tion in the thickness and amount of the membrane, and by a distinct improvement in all of the symptoms.

Intermittent Hydronephrosis Cured by Simple Puncture.—At a recent meeting of the Paris Société de Chirurgie, Hue (*Revue de Chirurgie*, 1893, No. 12, p. 1051) reported a case in which a large tumor had been present in the left hypochondrium for several years, but disappearing from time to time, either spontaneously or as a result of gentle pressure, its subsidence being attended with an urgent desire to urinate, followed by the evacuation of a large quantity of urine. For some time, however, the tumor had become permanent. A diagnosis of intermittent hydronephrosis was made, and transperitoneal puncture brought away clear fluid containing a good deal of urea. The tumor disappeared after this slight operation. It did not reappear, and the patient thereafter remained in perfect health. The opinion was expressed that the puncture relieved a cicatricial band consecutive to tabes mesenterica in infancy and compressing the corresponding ureter.

Sudden Blindness in the Course of Diabetes in Young Persons.—At a recent meeting of the Berlin Society for Internal Medicine, Litten (*Deutsche medicinische Wochenschrift*, 1893, No. 47, p. 1225) reported the cases of two children suffering from diabetes, in which blindness appeared suddenly. The one case was in a girl, seventeen years old, in whom vision had been impaired, and blindness developed in the course of a few hours. Upon inspection the crystalline lens of one eye was found to be quite opaque, and light-perception was lost in this eye. The lens of the other eye presented considerable striation, and vision was cloudy and obscure. The cataractous lens was successfully extracted, with subsequent improvement in vision. The second case also occurred in a girl, seventeen years old, who suddenly became blind in both eyes, with loss of light-perception In this case operation was not acquiesced in.

THERAPEUTIC NOTES.

The Pharmacologic Action of Amylene Hydrate.—As the outcome of a physiologic study, Harnack and Meyer (*Zeitschrift für klinische Medicin*, Band xxiv, Hefte 3, 4, p. 374) arrive at the conclusion that amylene hydrate, like alcohol, paralyzes successively all parts of the central nervous system, after preceding stimulation of individual parts. In herbivora quiet sleep is produced; in dogs and cats the symptoms of excitation and of profound intoxication in general predominate. In small, warm-blooded animals moderate doses are followed by a decline of 4° or 5° C. of temperature, larger doses by a decline of from 10° to 12° C. Even in dogs a decline of 6° may take place. The most pronounced reduction follows the use of a combination of amylene hydrate and certain tetanizing poisons—*e. g.*, santonin. The profound reduction of temperature increases the danger of death, which, on the other hand, is diminished by artificial heat. Respiration is at first increased in frequency and depth, but subsequently becomes progressively weaker to the point of paralysis of the respiratory center. In man the pulse-curve may present certain typical changes (diminution in the systolic elevation and disappearance of the dicrotism) after a dose of a dram. The blood-pressure sinks in warm-blooded animals slowly and progressively until death ensues. Amylene hydrate exerts a peculiar action upon striated muscular fiber; the energy of the frog's heart is for a time enormously increased; there then occurs a sudden fall, followed by irregularity and finally paralysis of the cardiac muscular fiber. The energy of the frog's muscle is at first notably increased, but subsequently there occurs paralysis. Amylene hydrate possesses the power of lessening and retarding the tetanizing action of certain poisons—*e. g.*, santonin, picrotoxin, strychnin. It would be worth while to study clinically the antithermic action of a combination of amylene hydrate and santonin. The results would appear to be promising, as amylene hydrate, when introduced into the stomach, diminishes the elimination of urea, lessening the metabolism of nitrogenous bodies in the organism. The subcutaneous injection of amylene hydrate is objectionable, being followed by increased elimination of urea, probably as a result of the energetic local action of the drug, which leads to abscess-formation and necrosis.

The External Application of Guaiacol to Reduce Febrile Temperature.— As the result of observations in twenty cases of various febrile conditions, including pulmonary tuberculosis, croupous pneumonia, typhoid fever, acute rheumatism, and puerperal infection, Stolzenberg (*Berliner klinische Wochenschrift*, 1894, No. 5, p. 109) arrives at the conclusion that guaiacol, applied to the skin, acts promptly and energetically in reducing temperature. The initial dose for adults should not exceed 30 minims. If this is well borne and a satisfactory reduction of temperature is not brought about, the dose may be cautiously increased, although it will rarely be necessary to exceed a dose of a dram. Moderate doses (not exceeding a dram) exert no unfavorable influence upon heart, kidneys, or other important organs. Larger doses may, in debilitated persons, give rise to manifestations of collapse. The decline in temperature is usually attended with free perspiration, which, together with the chill that occurs when the temperature subsequently rises, exerts so depressing an effect if frequently repeated as to preclude the recommendation of guaiacol for protracted use in the reduction of temperature. It was not observed that any influence was exerted upon the general course of the disease in which the agent was employed.

For Acute Coryza.—

THE BACTERIOLOGIC EXAMINATION OF DRINKING-WATER.

WHEN KOCH discovered his method of isolating germs by plate-cultures it was believed that the vexed question of deciding whether or not a certain water could be used by man without harm had been settled. Bacteriologists in all parts of the civilized world arranged their gelatin-tubes, cold chambers, and plates, and the good work began. The typhoid-bacillus should no longer hide itself in our daily drink. The chemist, with his estimations of free and albuminoid ammonia, chlorids, nitrates, nitrites, etc., had been unable to capture this great enemy of man, but the bacteriologist promised that he would succeed. What could be more easy? By means of the plate-cultures, each germ in the water could be isolated and grown in pure culture. After the latter had been obtained, the typhoid-germ, it was supposed, wears a uniform so distinct and characteristic that it can be recognized at sight. But it was soon found that the wily bacillus does not display any characteristic marks, if he has any. The bacteriologist was forced to admit that the task which he had undertaken was not so easy. Even the cholera-germ sometimes appears without his crook, and the typhoid germ forms a plainly visible mould on potatoes. Moreover, ordinary harmless saprophytic germs may have a properly fashioned curve and may form an invisible growth on potatoes. Having ascertained these facts, the bacteriologist changed his tactics. He no longer tried to isolate the specific microbe. He would decide as to the purity of a drinking-water by the number of germs present. But again there was trouble. One man thought that the limit for a safe drinking-water should be fifty germs per cubic centimeter, while another placed the limit at ten times this number. A learned professor at Jena closes a treatise of nearly three hundred pages on the bacteriologic examination of drinking-water with the following conclusions:

"The use of water which contains a specific pathogenic germ should be absolutely forbidden."

Then he goes on to say:

"The detection of specific pathogenic germs in water is surrounded by so many difficulties that its accomplishment is not likely to occur in the future."

With this statement he gives up the search for specific germs and takes up the number per cubic centimeter. Having decided that the proper solution of the question lies in counting the number of germs, he capitalizes the following:

"A large number of germs in the water of a well whose surroundings are questionable and of whose proper construction we are not certain suggests the possibility of infection. On the other hand, however, when the surroundings are favorable, when the well is properly constructed and covered, one may use the water notwithstanding the presence of a large number of germs."

If one of the most eminent authorities comes to the conclusions mentioned, it can hardly be a matter of surprise that some should regard the method ordinarily practised in the bacteriological examination of drinking-water as not altogether satisfactory.

In THE MEDICAL NEWS for June 14, 1890, p. 641, and in the *American Journal of the Medical Sciences* for August, 1892, p. 167, DR. VICTOR C. VAUGHN details the method used in the Hygienic Laboratory of Michigan University. This method consists briefly of the following steps:

First. The water is collected in sterilized bottles.

Second. Beef-tea tubes are inoculated with water, from one drop to one cubic centimeter being added to each tube.

Third. The inoculated tubes are kept at 38° C. for twenty-four hours.

Fourth. Many germs found in drinking-water will not grow at so high a temperature. Waters containing only such germs are pronounced safe. Certainly it must be admitted that a germ which will not grow at the temperature of the human body cannot possibly induce disease.

Fifth. Of the germs which do grow at 38° or higher, some are toxicogenic to animals, while others are not. Whether the germs in a given sample are toxicogenic or not is determined by injecting the prepared cultures subcutaneously or intra-abdominally in rats, guinea-pigs, rabbits, or mice.

Sixth. Waters containing only the non-toxicogenic germs growing at 38° or higher are reported as safe.

Seventh. Waters containing toxicogenic germs are condemned. In testing the virulence, a germ is not pronounced toxicogenic unless it be found growing and multiplying in the animal inoculated with it.

This method has been employed in the Hygienic Laboratory of the University of Michigan since October, 1888.

Recently BLACHSTEIN, working in the Pasteur Institute under the direction of METSCHNIKOFF (*Annales de l'Institut Pasteur*, No. 10, October, 1893) reports a method which may be condensed as follows:

First. Beef-tea is inoculated with the water.

Second. These tubes are allowed to stand for some days at ordinary temperature.

Third. From ½ to 1 c.c. of these mixed cultures is injected subcutaneously or intra-abdominally into guinea-pigs or rabbits.

Fourth. If the animal is killed by this injection the water is condemned.

BLACHSTEIN concludes his paper with the following paragraph:

"While I do not wish to draw any definite conclusions, I must emphasize the general fact that in all my researches waters which are suitable from the hygienic standpoint produce mixed cultures, when prepared as indicated, which are wholly inoffensive to animals."

It will be seen that there is nothing new in this method of BLACHSTEIN. It is crude compared with the Michigan method. There is no separation of those germs growing below 38° from those growing at this temperature or higher. While the former certainly cannot affect man, their cultures may contain chemic poisons which may kill the animals. There is no attempt in the method of BLACHSTEIN to ascertain whether or not any of the germs live after their introduction into the animal. This method is published as a discovery and is recommended as the best means of determining the purity of drinking-water, while, as we have stated, the other method, which contains whatever of good there is in BLACHSTEIN'S and excludes much that is doubtful, has been in use for more than five years.

KOCH, in his recent contribution upon the diagnosis of cholera (*Zeitschrift für Hygiene*, B. xiv), also adopts the inoculation-method in determining whether or not the cholera-bacillus is present in a given sample of water. He states that spirilla resembling cholera-germs may be found in many waters, and he recommends only two tests in deciding whether or not a given sample of water contains this bacillus: first, the indol-reaction, and second, the effect upon animals. We certainly do not see how much reliance can be placed upon the indol-test, because, as is well known, many germs, including some spirals, produce cultures which respond promptly to the indol test. This is true of the vibrio of METSCHNIKOFF, the FINKLER-PRIOR spirillum, DENEKE'S vibrio, and a comma-bacillus recently obtained from water by BONHOFF, likewise one by NEISSER. There are also present normally in the small intestines of man germs which produce indol. Every tyro in physiology knows that the production of indol through the activity of bacteria is constantly going on in the small intestines and is regarded as a part of intestinal digestion.

We have called attention to these methods of hygienic examination of water because the matter is one of great importance, and certainly it is time for us to dismiss the unscientific and useless procedure of determining the number of germs in a water without any reference to the kind of germs.

AN OPPORTUNITY FOR AMERICAN MEDICINE TO AID AMERICAN BIOLOGY.

EVERY physician who has the best interests of his profession at heart will admit that these interests will be advanced by bringing into medicine students of broad scientific education. The very commendable effort of some of our medical schools to advance medical education is a step in this direction.

Unquestionably, the students most desirable for medicine are those who have received a thorough training in the biologic sciences. Therefore, any-

thing which will increase the efficiency of biologic teaching must indirectly benefit medicine. But medicine, unfortunately, is still backward in extending to biology that fellowship so essential to successful results; and medicine does not offer the trained biologist a flattering prospect. It follows, then, that the biologist does not extend his energies into an unprofitable field, and, as a consequence, biology retains and medicine loses a valuable adherent. In fact, it too frequently happens that biology, instead of medicine, offers to the scientific physician an alluring field.

What may be done to invite into medicine this most desirable class of students? Elevate the entrance requirements and improve the course of study. Make provisions for well-trained and scientific physicians which will encourage them to remain in the profession, and to give to medicine the fruits of their labor.

Finally, coöperate directly with the biologists of America in any effort which will lead to a mutual advantage.

For several years a company of American biologists, under the direction of Professor C. O. Whitman, of the University of Chicago, have endeavored to put upon a sound working basis a coöperative marine biologic laboratory, at Wood's Holl, Massachusetts. From time to time Professor Whitman has set forth the aims of this institution, and has pleaded for the support and growth of the enterprise.[1] We earnestly recommend anyone who is interested in this subject to consult these articles for full details of the project.

Suffice it to here say that the Marine Biological Laboratory at Wood's Holl is a seaside research and instruction laboratory which is supported by the coöperation of certain American biologic schools and societies, and in which students are received for biologic instruction, and advanced workers are assisted in the prosecution of original researches. The pecuniary support of the Laboratory is entirely dependent upon private endowment; upon the subscriptions of interested institutions; and on the fees of the students; Government aid, for unfortunate political reasons, being neither proffered nor desired.

"The character and work of the Laboratory are shown by the following facts: The Laboratory is governed by a board of trustees on which the leading colleges and universities are represented. Its officers have been drawn from as many as *fifteen* of our higher educational institutions, and its membership has extended to *one hundred and thirty-one* colleges, universities, seminaries, academies, schools, and laboratories. During the last session forty-one investigators worked at the Laboratory, while the whole number, including students, was one hundred and eleven, representing seventy-two institutions and no less than seventeen States. Nearly *one hundred scientific papers and books* have resulted from work at the Laboratory, and have been published or are now in press."[1] Many of these papers are of profound interest to medicine.

Along with its other functions the Laboratory aims to become a center for research in *comparative physiology*, and, later, in *comparative pathology*. Assuredly, this means much for medicine.

As with every other altruistic enterprise in this egoistic age, the Laboratory is much hampered for funds wherewith to carry out its aspirations. It needs, moreover, the coöperation of more institutions—in this extensive coöperation everything is possible.

Is it not time for American Medicine to go on record as recognizing its sister science, American Biology, in support of this Laboratory of grand possibilities? Cannot every first-class medical college and medical society in this country afford to accept the invitation of Professor Whitman and his colleagues, and subscribe for a table at the Laboratory, or send some worthy student to profit by its advantages?

Let us at least make the acquaintance of a project which has every claim upon us.

EDITORIAL COMMENTS.

An International Sanitary Conference, for the consideration of the measures to be taken to regulate the pilgrim traffic in the Red Sea and Persian Gulf, with the view of preventing the importation of cholera to Mecca and its dissemination thence along the track of the returning Hajjis, which was originally to have been held in Paris on January 24th, was postponed to February 6th. It was expected that the Conference would occupy itself with tracking the cholera to its seats of origin—that is, Asia and India, dealing especially with the Meccan pilgrimage. There is reason to hope that the Sultan and the Shah of Persia will assist in arresting the development of cholera at its Asiatic ports of entry and posts of reinforcement.

[1] Extract from circular for "Local Committees."

As Mr. Ernest Hart has pointed out, Mecca is a main center from which European cholera spreads, and Hagar's well, where the Mussulman pilgrims wash and drink, is nothing better than sewer-water; in one day (June 26, 1893) there were 500 deaths at Mecca from drinking this water.

It seems agreed that the extinction of epidemic cholera in Europe may be secured without great difficulty. There are two ways of attaining this result: to insure everywhere perfectly pure drinking-water, and meantime put an end to the cause of insalubrity of the Meccan pilgrims. "Outside of this all measures are illusory; fumigations, railway and frontier quarantines, powderings and antiseptic fluids, are only vain ceremonies, simple sacrifices to popular ignorance, the idolatrous homage which dirt pays to cleanliness. The prime focus of cholera is India; its gates of invasion are the Indian fairs and the Meccan pilgrimage. Mecca is the reinforcing station of cholera between the Gulf of Bengal and Europe; it is there especially that the chief danger lies."

The measures required appear to be the installation of medical posts and posts of inspection at two points, the most important to be watched—Thor and Camaran. Every ship and every caravan of pilgrims should be accompanied by a medical staff furnished with all that is necessary for the purification and disinfection of the sick. Other matters for consideration are the reorganization of the sanitary service of India, the regulation of the great fairs of that country, the organization of a system of inspection of the pilgrims before leaving the Indian ports, and the curatorship of the sacred wells in which the Mussulmans bathe and drink at the same time.

The American delegates to the Conference are Dr. E. O. Shakespeare, Dr. Stephen Smith, and Dr. Preston H. Bailhache.

We await with much interest the outcome of the deliberations of this conference.

A Bill for an International Maritime Conference for the Better Care and Protection of Animals in Transit is now in the hands of the Committee on Inter-State and Foreign Commerce of the House of Representatives at Washington, and is one that in the interests of civilization and humanity should be passed. The bill provides:

"That the President of the United States be, and he hereby is, authorized and requested to invite the government of each maritime nation to send delegates to a quarantine conference that shall assemble at such time and place as he may designate, and to appoint seven delegates, one of whom shall be an official of the Treasury Department, one an official of the Department of Agriculture, one a representative of the steam marine, one a representative of the sailing marine, one citizen familiar with the cruelties to animals practised at sea, one citizen familiar with the importation of blooded horses, and one citizen engaged in the transportation of cattle, to represent the United States at said quarantine conference, and to fill vacancies in their number.

"It shall be the object of said quarantine conference to make, revise, and amend the rules, regulations, and practice concerning the transportation of animals at sea and their lives and slaughter in quarantine; for the proper construction of vessels for animals in transit; for the punishment of navigation companies or vessel-owners, their officers and employés, for cruelty to animals at sea; to make navigation companies or vessel-owners liable in damages for destruction of or injury to animals in transit; and to formulate and submit for ratification to the governments of all maritime nations proper international regulations, laws, penalties, and punishments for cruelty to animals at sea."

Here is a work for the anti-vivisection societies, and one wherein they will certainly be acting both in the interests of true kindness and of true science. A thousand times more suffering takes place in the transport of one herd of cattle from the plains of the West to Liverpool than has ever been caused by all the vivisection experiments of all time. But aside from the humane aspect of the question there is the sanitary side. The flesh of animals hideously tortured as these are is necessarily poorer and more dangerous food than that of healthy and properly-cared-for animals. It is well known that mental and physical pain and passion profoundly alter the tissues and secretions of animals, and may even render them toxic. The filth and crowding also intensifies and scatters every communicable disease. Medicine and noble sentiment here unite for a common work that needs to be done.

Liability for Injuries when Death follows Surgical Operations.—When death results from a personal injury as its direct and proximate cause the party responsible for the latter is liable for such death. In the case of Rettig *vs.* Fifth Avenue Transportation Company, recently decided by the Superior Court of New York City, General Term, which was an action brought to recover damages for alleged negligent acts causing injuries resulting in the death of the injured person, the defence was raised that death was rather caused by a surgical operation than by the injuries complained of. One of the attending physicians at the hospital to which the injured man was taken testified that he died from the result of his injuries, that his condition necessitated a surgical operation, which was skilfully performed, and that he died of the shock that followed. This evidence is declared admissible, and the court holds that the surgical operation and the consequences flowing from it in no manner relieved the transportion company from liability for the death as a result of the injuries inflicted by its negligence. Indeed, the court shows that it has been held that when a person who, through the negligence of another, has received an injury which, without a surgical operation, would cause his death, employs a competent and skilful surgeon, by whose mistake the operation is not successful, and the patient die, the wrongdoer is not shielded from liability by the surgeon's error; and this although the operation is the immediate cause of the death.

The Right Policy and the Right Principle.—We warmly commend to the earnest consideration of the members of the medical profession generally and of the American Medical Association in particular, the frank and outspoken language of a resolution recently adopted unanimously by the Ottawa City Medical Society to the effect that "under no circumstances shall the members of this Society consult with any homeopathic or other irregular practitioner." These are brave and noble words and will receive the indorsement of right-minded men

everywhere who recognize that there can be but one kind of physician and not halves and quarters and eighths and more minute fractions. The true physician, as we have more than once taken occasion to say, will use any remedy whose nature is capable of determination, whatever its source, independently of creed or dogma, if he but knows that it will save life, prevent disease, or relieve suffering. There may be homeopaths, and eclectics, and Thompsonians, and faith-curers and what not, but a physician should truly be a *physician*—nothing more, nothing less.

The First Chinese Medical College.—The first medical college worthy the name established by the Chinese Government was recently opened with formal ceremony at Tientsin. The project owes its origin to the intelligence and energy of the Viceroy of China and his wife, who constructed the necessary buildings and placed the direction in the hands of a distinguished graduate of the University of Dublin, selected by the late Sir Andrew Clark. The establishment of the college is attributed to the efforts of the Viceroy's medical attendant, Dr. Irwin, and to the influence of a Canadian woman, Dr. King. Some twenty well-educated English-speaking Chinamen have enrolled themselves as students, and the work of instruction has already been begun.

Liability of the Husband for Medical Attendance upon the Wife.—President Judge Hanna, in delivering the opinion of the Orphans' Court of Philadelphia, in the case of Waesch's Estate, says: The liability of the husband for medical attendance upon his wife, even although she has a separate estate, is too well settled to admit of argument. He is primarily liable, and her estate is liable only in case he be insolvent. If any balance then remains for distribution, the expenses he should have paid will be deducted from his distributive share.

The Cleveland Medical Society, although but a year old, seems established on a secure basis. Its membership already numbers two hundred and is growing rapidly. Permanent quarters for the Society and a library are projects well under way. The Society has done good work in uniting the medical profession of Cleveland into a harmonious and influential body.

SELECTIONS.

THE PRESS, THE QUACKS, AND THE PUBLIC.

AN address on this subject was delivered on Saturday evening at Toynbee Hall, E. C., by Mr. Ernest Hart. After referring in a general way to the growing power of the press, its accumulating responsibilities, and the admirable manner in which on the whole they were fulfilled, Mr. Hart turned to certain phases of journalistic responsibility which more especially came under his notice as a medical editor. He cited a considerable number of instances in which untold harm was effected at the present moment by the facility with which a considerable number of journals of high position and large circulation placed their columns at the disposal of a large class of persons who habitually practised open falsehood and palpable deceit, and worked untold harm among the more credulous sections of their readers. The vast circulation of the daily and weekly press, growing in importance, made this subject one of daily increasing moment, and he openly and directly charged a large proportion of the newspaper press of this country with sacrificing their duty, the honor of their calling, and the public interest to the inducements of palpable quacks and venders of either dangerous or insidious wares, offered at preposterous prices under palpably false pretences. The health of the people was being undermined, their morals were being sapped, and they were being robbed wholesale by unscrupulous venders of secret medicines; worse than this, a great proportion of religious papers and provincial papers sold their columns to persons who openly traded upon the weaknesses, the sins, and the fears of the married and unmarried of both sexes. The quack and patent-medicine impostor of olden times had a limited sphere of mischief; he had his cart or his stall in the market-place, and for the most part he was more ridiculous than harmful, but now limited companies were formed, syndicates were established, and great financial operations were undertaken to carry out an extensive system of preying upon the public with the aid of the vast publicity sold by the newspapers. Mr. Ernest Hart then read correspondence which he had had with the managers of some of the leading newspapers, in which some of them had frankly recognized their responsibilities in the matter, and described the precautions by which they protected their advertising columns from becoming the medium of such wholesale deceptions of the public. He referred, however, to the details of the Harness system of advertising, and to the advertisements and editorial puffs afforded quite recently to dangerous adventurers, free-lances in irregular medicine, and spoke of the career of the Anna Ruppert skin-lotions and to some of the results of the public medical lectures, freely reported in the daily papers. He asked that something of the same censorship should be exercised over the advertisements and editorials in the papers in dealing with medical matters as was admittedly exercised in ordinary advertisements relating to law, to commerce, and financial affairs. Advertisements putting forth evidently unfounded and impossible statements as to banking, or lotteries, or giving racing tips or gambling incitements, were not admitted into respectable papers. Why should the monstrous, dangerous, and palpably false statements and delusive promises put forward by the exploiters of secret medicines be alone accorded the unrestricted publicity of newspapers, great and small? Mr. Hart proceeded to say that the worst offenders were papers often full of religious pretension and social philanthropy. The evening papers, even in London, were great offenders, and the Sunday papers, from some of which he read extracts. Some Sunday and evening papers of the metropolis were setting the abominable example of publishing the monstrous statements of the quack advertiser as editorial articles in ordinary type. This was sinking to a lower depth of degradation than was customary, even in the lower types of British journalism, and was quite unworthy of papers having otherwise many claims to consideration.—*British Medical Journal, No. 1726, p. 208.*

PRESIDENT ELIOT ON INTERCOLLEGIATE SPORTS.

PRESIDENT ELIOT'S annual report was made public on the 20th inst. He says:

"In the highly competitive sports which give rise to exciting intercollegiate contests—namely, boat-racing, baseball, and football—there have been developed in recent years some evils of a serious nature. No sport which requires of the players more than two hours a day during the term time is fit for college use. No student can keep up his studies and also play his full part in any one of these three sports as at present conducted. There is something extremely inappropriate in the extravagant expenditure on athletic sports at such institutions as Harvard and Yale. In the game of football the players have been forced by public opinion to overtrain and overwork, until there is great risk of injury and even death. To become brutal and brutalizing is the natural tendency of all sports which involve violent personal collision between the players, as in football."

In the matter of remedies the President suggests the following changes:

1. There should be no freshman intercollegiate matches or races.

2. No games—intercollegiate or other—should be played on any other but college fields belonging to one of the competing colleges, or in the college town.

3. No professional student should take part in any intercollegiate contests.

4. No student should be a member of a university team or crew in more than one sport within the same year.

5. No football should be played until the rules are so amended as to diminish the number and the violence of the collisions between the players, and provide for the enforcement of the rules.

6. Intercollegiate contests in any one sport should not take place oftener than every other year.

REVIEWS.

MINOR SURGERY AND BANDAGING, INCLUDING THE TREATMENT OF FRACTURES AND DISLOCATIONS, TRACHEOTOMY, INTUBATION OF THE LARYNX, LIGATION OF ARTERIES, AND AMPUTATIONS. By HENRY R. WHARTON, M.D., Demonstrator of Surgery and Lecturer on Surgical Diseases of Children in the University of Pennsylvania; Surgeon to the Presbyterian Hospital, the Methodist Episcopal Hospital, and the Children's Hospital; Consulting Surgeon to the Presbyterian Orphanage. Second edition, thoroughly revised and enlarged, with 416 illustrations. Pp. 529. Philadelphia: Lea Brothers & Co., 1893.

THIS book, as its title expresses, is one which deals with more than is usually or legitimately included in a work upon minor surgery. It is probably this fact which has found for it so many friends as to necessitate the publication of another edition.

Part I is devoted to the subject of bandaging, the many methods of the application of the bandage being well illustrated by cuts, most of them from photographs. The various procedures of minor surgery—amongst which, however, are included tracheotomy and intubation of the larynx—are described in Part II. Here will be found also a very good account of the theory and practice of asepsis and antisepsis in the treatment of wounds, which the author has carefully revised for this edition, a description being given of all of the antiseptic agents now employed, as well as plain directions for the preparation of materials and dressings used in aseptic surgery. Parts III, IV, V, and VI, in which are described respectively fractures, dislocations, ligation of arteries, and amputations, are written in as plain and practical a manner as the rest of the book, and are amply illustrated with well-chosen cuts.

We congratulate Dr. Wharton upon the success which has attended his book, and we feel sure that the additions to this second edition will bring to it even greater success.

THE MODERN CLIMATIC TREATMENT OF INVALIDS WITH PULMONARY CONSUMPTION IN SOUTHERN CALIFORNIA. By P. C. REMONDINO, M.D. Detroit, Mich.: George S. Davis, 1893.

THOSE who think of sending patients to California will do well to read Dr. Remondino's excellent little book. The advice given is good and the meteorologic and epidemiologic statistics cited will aid in determining what cases to send to that region. There are, perhaps, too many and too long quotations for a booklet of 126 pages, and we would have wished the advertisements of nostrum and of real-estate omitted from the fly leaves. For this, however, publisher and not author is responsible.

CORRESPONDENCE.

THE TERMS "INFECTIOUS" AND "CONTAGIOUS."

To the Editor of THE MEDICAL NEWS:

SIR: Your editorial in the issue of THE MEDICAL NEWS for January 27th on "The Infectiousness of Tuberculosis" revives a feeling which has often occurred to me of late, and which perhaps has also occurred to others, that the time has come for an authoritative expression on the part of those best qualified to judge—that is, the pathologists—as to the exact sense in which the terms *infection* and *contagion* should be used. When myself a teacher of pathology some years ago, following Wagner, and, I believe, most German pathologists of that day, I taught that an infectious disease is any disease due to a specific cause, whether such cause originates in another person having the same disease or from some external source, as the atmosphere or soil. Then, after the bacterial origin of these diseases came to be admitted, the definition of an infectious disease became a "disease caused by the implantation and proliferation of a pathogenic microörganism," not including, however, the parasitic skin-diseases. Thus defined, infectious diseases are divisible into two groups, *contagious* and *miasmatic*. Contagious diseases are those derived from others having the same disease, while

miasmatic are those of which the cause originates externally. Of contagious diseases typical instances are, of course, smallpox and scarlet fever, while a typical instance of miasmatic disease is malarial fever. Thus infectious diseases include contagious diseases, and while every contagious disease is an infectious disease every infectious disease is not a contagious disease.

Modern studies have greatly altered the list of diseases in each of these categories, that of the contagious diseases having been enlarged by the addition of many formerly included among miasmatic, while the latter have grown correspondingly less numerous. Thus yellow fever and even typhoid fever, always regarded as infectious but formerly classed as miasmatic, are now included among the contagious, so that malarial fever remains essentially the sole miasmatic disease. To the former category tuberculosis has now to be added, being both infectious and contagious, through the tubercle-bacillus, which is the contagium or specific cause, the sputum being the contagium-bearer. The idea of contact implied in the etymology of the word contagious is the misleading idea. The absurdity, however, of applying the term contagious to the diseases only communicable by *actual* contact is apparent, because it is well known that smallpox can be communicated from one person to another without actual contact; and if the term were restricted to such cases as actually originate by contact, smallpox would sometimes be a contagious disease and sometimes not.

The term miasmatic-contagious was at one time applied to diseases of which the true origin was doubtful or which might be both contagious and miasmatic.

This use of the terms may be all wrong in the light of modern knowledge, but in such matters as these the pathologists should give the stamp to our thought, and this would seem to be a suitable time for them to agree upon such use of these terms as our modern knowledge demands, and give those who desire to use them accurately the benefit of their *united* opinions. The idea of what constitutes an infectious disease seems pretty definite. But what shall we do with "contagious"? Shall it be made to mean the same as infectious? Certainly the parasitic skin-diseases are contagious, and contagious in the strict meaning of the word, but I believe they are not regarded as infectious.

JAMES TYSON, M.D.

1506 SPRUCE STREET.

THE OPERATION OF VAGINAL HYSTERECTOMY BY ENUCLEATION DUE TO LANGENBECK.

To the Editor of THE MEDICAL NEWS,

SIR: I find on referring to the literature of the subject, that the operation of vaginal hysterectomy by enucleation (see MEDICAL NEWS, February 10, 1894) is *not* original with Dr. Pratt, but is a revival of the old operation of Langenbeck (1813).

Wrisberg and Monteggia *first recommended* total extirpation in carcinoma of the uterus. The first operations of this kind (Marschall, 1783; Langenbeck, 1813) were performed on prolapsed uteri; strictly speaking, were not total extirpations.

Langenbeck's successful operation exerted great influence, and his method of subperitoneal enucleation of the uterus long dominated the opinions of his followers.

Abstract of Langenbeck's method. "I now came to that portion of the uterus, which, seen from the front, was inserted into the peritoneum as into a cloth. I also separated very accurately the substance of the uterus from the peritoneum, without cutting it, because otherwise the intestines might have protruded, and constantly drew out the uterus. I continued this separation to the upper rounded border of the fundus uteri, and then cut the uterus out of the peritoneum in such a way that a small piece, which seemed to be perfectly healthy, remained connected with the peritoneum. This was consequently a true enucleation of the uterus out of the peritoneum, so that the latter, in connection with the vagina, formed an empty bag." The ovaries, which Langenbeck thought he had removed, were found at the autopsy.

In 1822 Sauter performed the first extirpation of a carcinomatous uterus *in situ* through the vagina. He first separated the fornix from the uterus and then attempted to enucleate the uterus from its peritoneum. The operation was unsuccessful and the bladder was injured. He then opened into the anterior peritoneal fossa and divided the lateral connections of the uterus with the tubes and broad ligaments; then grasped the fundus, turned it over, and separated its last connections with the posterior fornix. The intestines were replaced, the vagina tamponned; not more than one and a half pounds of blood were lost. Complete recovery followed, but the woman died four months later, of pulmonary edema.

Récamier's much more perfect method (1829) is distinguished from that of Sauter by the fact that, after opening the anterior peritoneal fossa, the upper two-thirds of the broad ligament alone were removed, but the lower third and uterine artery were grasped between the index finger and thumb and ligated. Hemorrhage was slight and removal of the ligatures followed on the tenth day. In 1830 Delpech recommended a combination of the hypogastric and vaginal methods.

Malgaigne's (J. F.) proceeding.[1] "Circularly incise the vagina as far down as the disease allows, gently and cautiously down to its external cellular tunic; dissect it up, reflecting it like the skin in an amputation; push back the bladder or intestines, if you meet them, beyond the reach of the instruments; detach the womb if possible by enucleation and without opening the peritoneum; or open that membrane cautiously; and lastly, divide the lateral attachments of the womb by which its vessels pass to it. The lateral attachments may be all tied together before they are cut; or, better, the arteries may be tied immediately after they are divided; and lastly, the operation is terminated, uniting by suture the wound in the vagina, so as to shield the peritoneum from contact with the air. Langenbeck once had recourse to an analogous proceeding; having found the bottom of the wound healthy, he carefully separated from it the diseased parts, and thus avoided opening the peritoneum; the woman recovered." Very respectfully,

ROBERT REYBURN, M.D.

WASHINGTON, D. C.

[1] Op. Surg., transl. by F. Brittan. Philadelphia: Blanchard & Lea, 1851. Page 551.

TO PREVENT THE SPREAD OF TUBERCULOSIS.

To the Editor of THE MEDICAL NEWS,

DEAR SIR: The exceedingly interesting discussion on "The Contagiousness of Tuberculosis," reported in THE NEWS of February 10th, is probably the most important deliverance on the subject which has recently been given to medical science.

Granting that the dried sputum is the infecting material, it seems to me that the disinfection of public vehicles is of even greater importance than the disinfection of houses. The abominable habit of spitting in street-cars is probably one of the most prevalent sources of contagion. It is true that in this city notices are displayed in most of the street-cars, forbidding the habit, but as the officials, from president to conductor, appear equally uninformed and indifferent, no attempt is ever made to enforce the rule.

If the Board of Health would use its influence with the higher officials of the car-companies, and the profession would endeavor to interest individual stockholders in the matter, it might be possible to have instructions issued to conductors to call the attention of the filthy offenders to their misconduct; and if these instructions were carried out effectually, the spitters would probably prefer to abandon their habit rather than stand the constant staring to which they would be subjected by their fellow-passengers, when called to account.

Is not the tuberculous spitter as real a source of danger, under the circumstances, as a smallpox patient? The latter would clear a car in an instant, if his disease were recognized, while the consumptive spitter continues undisturbed to disgust the decent among his fellow-passengers, and scatter poison absolutely broadcast as he goes. Is there no remedy for this?

Yours respectfully,

GILBERT H. SHEARER.

2128 ARCH ST., PHILADELPHIA.

ORCHECTOMY FOR HYPERTROPHY OF THE PROSTATE.

(A Second Note.)

To the Editor of THE MEDICAL NEWS,

SIR: A short time ago (see THE NEWS, December 30, 1893, p. 748) I stated that I had removed both testicles from an old man suffering from enlarged prostate, in accordance with the suggestion of Prof. J. William White. Eight weeks have elapsed since the operation, and the patient is practically cured.

In another case, in which sections of the vasa deferentia were removed, I can as yet see no change.

Two weeks ago I removed the testicles of another old man, who stated that he had not urinated except through a catheter for two years. Since the operation he has passed about an ounce of urine naturally several times every day.

Further results will be published hereafter.

I trust other surgeons will publish brief reports of their experience with this promising procedure.

Respectfully,

FRANCIS L. HAYNES.

LOS ANGELES, CAL.

Suicide.—A committee of the New York Medico-Legal Society, to which was submitted the question of the repeal of the existing law making punishable unsuccessful attempts at suicide, recently presented the following report, which was approved and ordered to be submitted to the Legislature of the State and the Constitutional Convention:

1. It [the law] is wholly indefensible from the standpoint of this great principle, that all penal laws should have for their object the deterring rather than the punishment of crime.

2. It in effect repeals the former laws making suicide a crime, and makes its unsuccessful attempt punishable only; so that its effect is to stimulate the would-be suicide to higher efforts toward self-destruction to avert the punishment it visits only upon failure.

3. The act, therefore, instead of serving as a deterrent to the commission of crime, which should be the aim of penal legislation, is one which, in its whole scope and effect, incites to and probably actually increases the volume of this crime.

4. Civilization, in the recent centuries, has regarded and treated suicide as a crime, and has attempted to so frame its penalties as to act as a deterrent upon the minds of those who sought or have contemplated it.

The majority of mankind would be influenced by any post-mortem punishment that would bring disgrace or reproach upon the names, family, or friends of the suicide.

The existing statute ignores the universal recent judgment of the race, in relieving the successful suicide from all such restraints, with their conceded deterrent effects.

5. A large proportion of suicides are confessedly those laboring under insane delusions. Unsuccessful attempts by such, under the existing statute, are pitiful examples of the incongruity and unwisdom of the law in its practical operation.

6. It is claimed, and with great propriety, that the present statute is practically inoperative.

We respectfully submit that this enactment should no longer remain among our criminal statutes.—*Medico-Legal Journal*, vol. xi, No. 3, p. 331.

Dr. August Hirsch, Professor of Special Pathology and Therapeutics and of the History of Medicine in the University of Berlin, died January 28th, at the age of seventy-seven years. His most important publication was a handbook of Geographical and Historical Pathology.

Dr. T. Cranstoun Charles. Lecturer on Practical Physiology at St. Thomas' Hospital Medical School, died on January 24th, in the forty-fifth year of life. He was the author of a handbook of Physiological Chemistry.

THE RELATION BETWEEN THE GROSS ANATOMY OF THE APPENDIX AND APPENDICITIS.[1]

BY JOSEPH D. BRYANT, M.D.,
OF NEW YORK.

THE anatomic peculiarities of the appendix that affect directly the symptomatology of appendicitis relate especially to the location, direction, and extent of the appendix. The local symptoms are chiefly modified by these characteristics of the organ. The emphatic symptoms belonging to this category may be briefly stated as pain, tenderness, tension, and tumor.

The situation and character of the pain, together with its reflex manifestations, comprise its important elements as modified by the individuality of the diseased appendix causing it. If the pain be dull and throbbing, and be influenced but little, if any, by respiratory movements, the involvement of connective, rather than serous tissue, is indicated. Later in the case, however, the supervention of serious painful phenomena may be slowly or quickly announced.

Appendicitis with primary fibrous-tissue involvement is necessarily rare, as then the appendix is extra-peritoneal, or is completely environed by inflammatory adhesions, the result of repeated attacks. In but three instances of one hundred and forty-four autopsies made for other than appendicular trouble was the appendix found outside of the peritoneal cavity. In one of these it was above and behind the cecum and colon; in another, behind and near the inner border of the colon, extending even to the liver; and in the third it was behind the colon near the outer border. It is in accordance with the well-known law that the character of pain is modified by the kind of tissue involved, to assume that had either of these appendices been diseased, the primary pain would have been of the connective-tissue type, continuing so until peritoneal involvement had ensued, either by extension of the inflammatory process, or of abscess-rupture. It was my good fortune but a few years ago to meet with a well-pronounced case of this kind in Bellevue Hospital. In this instance, a dull throbbing pain had been present for some time beneath the ascending colon, with tenderness and induration. Suddenly the acute agonizing pain indicative of peritoneal involvement occurred, quickly followed by peritonitis and rapid death. At the time of the consultation I ventured to predict: (1) the presence of a diseased appendix behind the cecum and colon; (2) extensive connective-tissue inflammation and abscess; (3) rupture of the abscess into the peritoneal cavity. The results of the autopsy justified each prediction.

In many cases of recurrent appendicitis the familiar pain of acute attacks is not present at the outset, and may not appear at all; and, too, respiratory movements cause but little, if any, additional infliction. I saw such a case but a few days ago during recovery from a fourth attack, with intervals of one year each. It is, of course, superfluous to say that primary intra-peritoneal appendicitis causes acute pain, for this is the typical manifestation of the disease. It is proper to add, however, that the mobility and length of the appendix have much to do with the severity and extent of the pain, and also with the rapidity of the diffusion of the poisonous products of the disease. All are aware that the appendices of some are comparatively "free" in the peritoneal cavity, their movements between the contiguous intestines being limited only by their mesenteries, or their attachment to the cecum. The free extremities of such as these are often observed extending upward from between the intestinal loops, and at this time can be aptly compared to the erect position of the deadly cobra when prepared to strike.

Let us now glance for a moment at the records attesting the freedom of movement of intra-peritoneal appendices. In sixty-six examinations, twenty-six (40 per cent.) were "free," in that one-half of the entire length was surrounded by peritoneum. The remaining forty had mesenteries varying from three-fourths to more than an inch in length. Surely the length and the freedom of movement of a diseased intra-peritoneal appendix exercises an important influence on the intensity and area of the pain, and the rapidity of the diffusion of the disease-producing elements. Dr. Reginald Fitz, in his oft-quoted and classic article, published in the *American Journal of the Medical Sciences*, October, 1886, says: "Sudden severe abdominal pain is the most constant first decided symptom of perforating inflammation of the appendix." As a proof of the fact, he shows

[1] Abstract of a paper read at the meeting of the N. Y. State Medical Association, February 7, 1894.

that this manifestation occurred in 216 of 257 cases, or 84 per cent. of the number. If we now turn our attention to the percentage of "free" appendices, and those with mesenteries of more than an inch in length, we also find their sum to be 84 per cent. of the entire number. Certainly this similarity of percentages is, at the least, a strange coincidence.

While it is doubtless true that the situation of the pain is regulated to some extent by the location and direction of a diseased appendix, still, neither time nor utility will permit me to indulge in hair-splitting distinctions in this regard, based on the fact of the extension of the appendix outward, downward, inward, etc., as this feature alone possesses no practical importance, except when the appendix extends beyond the usual limit. It may not be amiss to add, in this connection, that the appendix runs inward in about 25 per cent.; that it is curled behind the cecum in about 20 per cent., and that it extends into the pelvis in 14 per cent. of all cases. The average length (post-mortem) of the appendix in the male is $3\frac{1}{2}$, and in the female $3\frac{1}{10}$ inches, as deduced from 144 examinations. The importance of the frequency (14 per cent.) of intra-pelvic extension should not be considered lightly. Nor can the differences in the length of the organ, as between the sexes, be deemed insignificant, when it is noted that the half-inch difference between them causes the appendix of the male to enter the pelvis twice as often as that of the female. The clinical importance of intra-pelvic extension of the appendix cannot be gainsaid. In a diseased appendix there located the pain may be nearer the hypogastrium, and, too, it may involve the pelvic peritoneum, and modify the action of the pelvic viscera during functional activity. And especially are these facts true if the extremity of the appendix be the portion involved by gangrene or perforation.

Thus far only direct pain has been considered, of both the acute and dull types. Reflex pains, while less important than the direct, are, nevertheless, of great diagnostic significance. Frequently during the course of an attack, and especially at the outset, reflected pain may be present in almost any part of the abdomen. And, too, it is observed not infrequently in the testicle, perineum, rectum, thigh, lumbar region, etc. In fact, referred or reflex pains may occur in the distribution of any spinal nerve directly involved by the disease. Fitz has shown that in 213 cases of appendicitis pain was present in the right iliac fossa in 48 per cent.; in the abdomen in 36; in the hypogastrium in 5; in the umbilical region in 4; in the epigastrium in 2; and 1 per cent. each in the stomach, hepatic region, left iliac fossa, and right hip and groin. I myself treated a case on June 23, 1886, in which the pain was referred to the umbilical region only. That this was a genuine case cannot be gainsaid, as the appendix was found to be perforated and was removed. The anatomic reason for the occurrence of these reflex pains resides in the well-known influence exercised by the abdominal sympathetic ganglion on the contents of the belly. A misplaced appendix, or a wandering cecum, will account for an unusual pain-site in a few instances. Without amplification, it is sufficient to say now that pain in the right testicle, with or without its retraction, indicates the direct involvement of the genito-crural nerve. The same may be said also of the ilio-inguinal, and the anterior crural, when pain is referred to their respective distributions, in connection with recognized or suspected appendicitis.

Tenderness, the second of the inherent manifestations of appendicitis, may be either local or general, superficial or deep, keen or dull, depending on the extent, location, and character of the inflammation and the variety of the tissue involved by it. If the extra-peritoneal connective tissue be first involved, as when the appendix is located behind the colon, or behind a cecum not surrounded by peritoneum, or outside the peritoneum elsewhere, and, perhaps, between the layers of the broad mesentery of the appendix, the tenderness at the outset is local, deep-seated, and dull. That such cases as these are rare is obvious, on account of the great infrequency of appendices so placed. Quickly, however, the dull tenderness is supplemented and obscured by the acute variety, due to the rapid extension of inflammation to the contiguous peritoneum. The rapidity of the supervention of the acute pain is in direct proportion to the gravity of the lesion and the amount of connective tissue involved by it. Dull tenderness of much duration is indicative, therefore, of a post-colon position of the appendix, and especially is this true in the absence of a meso-colon, which, according to Treves, happened in 52 per cent. of the subjects examined by him.

Acute tenderness is, of course, strong proof of the involvement of the peritoneum, and when it is circumscribed and marks the outset of the attack, its location may be accepted as indicating the site of the initial lesion. If this statement be true, then, indeed, no definite point of tenderness can be established that may be regarded as diagnostic of this disease. The varying directions of the appendix already cited; the differences in its length, and in the situation in it of the point of greatest disease; together with the doubt as to the location of the cecum from which it arises, all conspire to make the establishment of such a point impossible, and a reliance on it impracticable and misleading. Of general tenderness I will say but little, as it cannot be regarded as indicative of a circumscribed

process, and is, therefore, not to be considered as of much practical bearing on the arrangement of the appendix. It is proper, I think, to say that in those cases of appendicitis observed by me, in which the diseased appendix was "free," the area of tenderness was far greater than in those not so freely movable.

The term tension refers mainly to tension of the abdominal walls—a tension that may be limited to the side of the attack, or be more or less general, according to the extent of the inflammation associated with it. The presence of this tension-phenomenon is of beneficent significance and should incite the profoundest respect of the most skeptical minds. The motor nerve-fibers that animate the abdominal muscles are from the lower intercostals, and are intimately connected with the sympathetic supplying the abdominal viscera, through the lower thoracic ganglia from which the splanchnic nerves are derived. As a result of this arrangement, in acute peritonitis the muscles of the abdomen become quickly and firmly contracted, and thus shield the underlying viscera from external force and keep them as quiet as it is possible to do by physical means alone. Tension of the right rectus abdominis muscle in appendicitis is an early and important symptom and indicates the presence of limited peritonitis, and fulfils the conservative purposes already stated. And for these reasons the left rectus goes on guard too, when its subjacent viscera are similarly involved. Muscular tension in this disease is not limited entirely to the abdominal walls, as the psoas and iliacus muscles also contract from nervous involvement or direct implication, causing flexion of the thigh. The bladder and rectum often become fretful, especially if the diseased appendix extends into the pelvis or is attached to the peritoneum at its brim. The cremaster muscle exercises its prerogative on the testicle, if the genito-crural nerve is implicated.

Tumor is a symptom of dual importance on account of its diagnostic and therapeutic significance. The former attribute alone concerns the subject of this paper. That the situation and extent of the diseased appendix has much to do with the location and the determination of the presence of tumor cannot be denied. Generally speaking, the location of the tumor indicates the situation of the lesion, and it is especially significant if the tumor be small, firm, deep-seated, and fixed in its position. If, on the other hand, it be large, not firm, superficial, and movable, its bearing on the site of the initial disease is of a general character only. When present, according to Fitz, tumor is detected by palpation from the first to the eighth day of the attack, inclusive. In 24 cases it appeared—in 1 on the first day; in 3 on the second; in 4 on the third; in 2 on the fourth; in 4 on the fifth; in 5 on the sixth; in 4 on the seventh; and in 1 on the eighth day. The third, fifth, and sixth days are noticed to be the most prolific ones. Tumor may be early present and yet not be detected till later in the disease, owing to its obscure position, as when associated with a diseased appendix that is located behind the cecum (22 per cent.); when placed behind the colon (2 per cent.); when extended into the pelvis of the intra-pelvic portion to the diseased part (14 per cent.); with a tympanitic cecum, and with general tympanites irrespective of its location. In the intra-pelvic cases tumor may often be detected in the pelvis and not elsewhere, by rectal or vaginal examination. Still, in these cases, tumor may escape the vigilance of the closest scrutiny.

Owing to time-limit I have dwelt only on the leading cardinal symptoms, leaving consideration of the rarer and more curious manifestations for another occasion. In closing, permit me to submit the following conclusions for your consideration:

1. That the location, direction, and extent of the appendix have an important bearing on the clinical history of appendicitis.

2. That the well-recognized variations of the appendix in length, direction, and location, and the varying site of the cecum, and of the seat of the disease of the appendix, make the establishment of a definitely-seated diagnostic point of tenderness unwise and misleading.

THE PATHOLOGY OF LOCOMOTOR ATAXY.[1]

By SYDNEY KUH, M.D.,
PROFESSOR OF NERVOUS DISEASES, CHICAGO POST-GRADUATE MEDICAL SCHOOL; ATTENDING NEUROLOGIST, HOME FOR AGED JEWS; NEUROLOGIST, UNITED HEBREW CHARITIES DISPENSARY, CHICAGO, ILL.

Locomotor ataxy has found its place in all of our modern text-books on nervous diseases amongst the lesions of the spinal cord. As our knowledge of the pathologic changes in tabes became more exact we found that the spinal cord was not by any means the only part of the nervous system affected. Sclerotic lesions of the posterior spinal roots of the peripheral, spinal, and cerebral nerves, occasionally, also, alterations in the nuclei of cerebral nerves, were discovered. The substance of the brain, it would appear from these reports, is not, as a rule, diseased.

An attempt to explain the genesis of the symptoms in almost any case of locomotor ataxy will soon convince us that comparatively few of them can be attributed to the spinal cord. We know that such disturbances of the functions of the bladder, rectum, and genital organs, as are com-

[1] Read before the Chicago Medical Society, February 5, 1894.

monly found in tabes, can be caused by spinal lesions; they do, however, also occur in diseases of cerebral origin.

Westphal's symptom—the disappearance of the knee-jerk—seems to be undoubtedly a spinal one. The discoverer of this most important sign was fortunate enough to be able to localize its origin very exactly in the spinal cord, his researches proving that degeneration of a region called by him the "Wurzeleintrittszone," by French authors "bandelettes externes," was associated with loss of the knee-jerk.

As to the localization of the most important symptom of this disease, the one from which it was named, we know nothing of a positive nature whatsoever. Attempts have been made to explain it by assuming it to be due to sensory disturbances in the joints. All of them have, in my opinion, been decided failures. If there were a connection between these two symptoms, then every case with marked ataxy ought also to present marked sensory disturbances, and any case with slight sensory disturbances only slight ataxy. This is not the case. I have myself seen a case in Heidelberg with very marked incoördination of the movements of the lower extremities. The man has repeatedly been subjected to a very exact examination within the last few years, which has never revealed any sensory disturbances which could have caused the ataxy. Other cases are on record presenting complete anesthesia and not a trace of incoördination.

Jendrassik has called attention to the fact that, leaving locomotor ataxy out of consideration, there is no case on record which proves that ataxy can be caused by a spinal lesion. Some few observations, it is true, are quoted as proofs of this statement, but in some of them the brain was never examined; in others, when this was done, cerebral changes were found as well as spinal lesions.

Never, to my knowledge, has anybody succeeded in producing incoördination of movement by experimentally injuring the spinal cord. There are quite a number of cases on record in which degeneration of peripheral nerves has been found in ataxic subjects. Here, too, it seems that the brain was never examined.

Pitres has reported a case of pseudo-tabes with ataxy, in which spinal cord, spinal roots, and spinal nerves were found to be intact. Does not this observation clearly demonstrate that we must search for the lesion higher up in the nervous system, in the medulla oblongata, pons, or brain.

Glotz's researches have induced him to assume the existence of a center for coördination above the spinal cord. He describes the alterations of motility in his dogs after removal of portions of the brain by comparing the movements to the "Hahnentritt," the step of a cock, a name which is frequently used in Germany in designating the walk of the ataxic. Wernicke and Kahler have seen cerebral lesions followed by ataxic movements exactly like those in tabes, and within the last year or so a similar asssociation was described in a tumor of the frontal lobe—if I am not mistaken, by Bruns. I have seen two cases of this nature, one some years ago, without, however, being able to give the details today. A second was kindly referred to me for examination by my friend, Dr. Carl Beck, only a short time ago. The patient, J. B., is a waiter, fifty years old. His parents are alive, his mother having had a stroke of apoplexy when seventy years old; the father is said to be healthy. B. has partaken of stimulants somewhat freely. In 1870 or 1871 he had a chancre, followed by exanthemata. He is married, but has no children. He has been ill for the last two years. At first the toes of the right foot became cold and numb. He was then delirious for about two weeks, and it is impossible to ascertain whether or not he had delirium tremens. At the end of this time he attempted to get up at night, but fell, as both of his legs were paralyzed. The arms were not weakened; his sphincters acted perfectly well; he was not unconscious; there was no anesthesia. After five or six days he was so far improved that he could get around with the assistance of two canes. The left limb soon regained its normal power; the right one, however, caused him a good deal of inconvenience, as he had intense pain in it whenever he tried to stand or walk, but it too did not remain paretic, nor did it become rigid. Seven or eight months after this there was a syphilitic ulcer on the right shoulder. Pain began to make its appearance in the right arm and the right upper portion of the trunk, being intensified by every movement. Then the speech became impaired; there were paresthesiæ in the right arm; and movements became clumsy. In the right side of the head he always has a painful sensation of heat. One and a half years ago he had double vision for about four months, which disappeared spontaneously. He never had headaches, and did not vomit. The memory is not impaired, nor have the functions of the higher senses suffered.

The right pupil was larger than the left, and the reaction to light was lessened on both sides. Marked tremor of the tongue and facial muscles existed. The speech is thick. There is paresis of the right arm, but no atrophy. The deep reflexes are less marked on the right than on the left side. Pronounced ataxy of the right arm exists. Sensibility is normal. In the legs there was also ataxy on the right side, and the knee-jerk was lessened on both sides. When the patient closes his eyes and places his feet close together, he sways slightly.

The abdominal reflexes are absent. The most scrutinizing examination reveals but one additional symptom, but this one alone enables us to reach a diagnosis. There is a choked disc on the left side. Hence this is a case of tumor of the brain, with marked ataxy of the right extremities.

One more point deserves to be mentioned in this connection. Although few, there are some cases of locomotor ataxy in which the onset of the incoordination is quite acute. I have been fortunate enough to see two cases of this kind. It will hardly do to attribute a symptom that appears quite suddenly to the chronic, very slowly progressing lesions, such as we find in the spinal cord. Of late, attempts have been made to improve the condition of the ataxic by systematically practising movements, and they have been very successful. Can we learn with our spinal cord? Can practice decrease the number of degenerated fibers in the posterior columns?

A part of the sensory disturbances in locomotor ataxy may readily be explained by lesions of the posterior columns; others, however, it appears to me, are due, to a change not in the conducting but in the perceiving organs. In this connection I would mention the symptoms of allocheiria, polyesthesia, and after-pain, all of which are to me intelligible only if I assume that the function of apperception and not that of mere conduction is impaired.

The symptoms just enumerated have very probably their origin in some part of the nervous system other than the spinal cord. There is another series, no less numerous than this, which is surely due to extra-spinal lesions. Amongst these, ocular disturbances are both the most important and the most frequent, very often preceding by years every other sign of illness. I refer to the atrophy of the optic nerve, to ophthalmoplegia interna and externa. Eulenburg has compiled statistics on the frequency of these symptoms, comprising sixty-four cases of locomotor ataxy. In these he found strabismus divergens 19 times, 4 times associated with paralytic ptosis; strabismus convergens, 6 times; mydriasis, 6 times; myosis, 28 times; amblyopia, 31 times.

Topinard has examined 102 cases of tabes and found amblyopia in fifty-one, or exactly 50 per cent. These statistics ought to be considered sufficient proof of the fact that the ocular disturbances are more than chance complications, that they are very important and constant symptoms, as constant almost as any found in tabes. I have mentioned the impaired reaction and increased or decreased size of the pupils amongst the extra-spinal, or rather, cerebral symptoms, as I am convinced that this is the correct localization for them. Although we know exactly where to search for the so-called cilio-spinal center in the spinal cord, nobody has, to my knowledge, ever found any lesion of this portion in a case of locomotor ataxy. Bramwell is certainly fully justified in attributing the loss of pupillary reaction to light and the decrease in size of the pupil to cerebral changes.

There are quite a number of other symptoms of clearly cerebral origin not infrequently found in ataxy, such as atrophy of cerebral, auditory, olfactory, and other nerves; paralysis of accommodation, hemiatrophy of the tongue, paralysis of the sensory or motor portions of the fifth nerve, lightning-pains in the head, attacks of vertigo, transient apoplectiform seizures, transient hemiplegia, convulsions in cases which never develop general paralysis (Kahler), various forms of insanity, besides the exceedingly frequent combination with paralytic dementia, drowsiness, headache, hyperemia cerebri, and increased irritability. Steinthal has noticed, and Erb confirms his observations, that patients suffering from locomotor ataxy are very frequently remarkably gay and satisfied with their fate. Athetosis has been observed by Cruveilhier, Hammond, Leyden, Laquer, and others.

If cerebral changes are as common in locomotor ataxy as the frequency of cerebral symptoms would seem to make probable, why are they so rarely described? Whoever has attempted to find microscopic lesions in a brain without knowing just where to look for them will not hesitate to answer this question. It is an undertaking that requires more patience and more time than most observers wish to give to it. The difficult and tedious task has, however, been undertaken in a few cases within the last few years. And the results are just what we must expect if we consider the symptoms. In every case examined, diffuse changes in the cerebrum have been discovered. Jendrassik was the first to undertake these researches. He examined the brain of two individuals who had suffered from locomotor ataxy, but had not presented any symptoms of general paralysis, and in both cases he found cerebral lesions. Somewhat later I had occasion to control his results in another case in which the inspection at the time of the post-mortem examination did not indicate that the brain was diseased. Unfortunately this case was not a pure one, as the microscope revealed the existence of diffuse syphilitic lesions in the membranes of the brain and spinal cord. This was the first time that meningitis syphilitica had been found associated with the typical tabetic degeneration in the posterior columns. Since then a number of similar cases have been published. Kraus has recently communicated the result of his most diligent and exact researches on the pathology of locomotor ataxy. Unfortunately, like most of his predecessors, he, too, has not taken the trouble

to make a microscopic examination of the brain; but even so, his work is of the greatest importance to us. He has examined the brain macroscopically thirteen times and has found changes in the brain-substance proper, the cerebral nerves, or the membrane with the naked eye, thirteen times. The lesions discovered were:

	TIMES.
Atrophy of the optic nerve	2
Atrophy of the olfactory nerve	1
Atrophy of the brain	4
(Perhaps also present in a fifth case.)	
Pachymeningitis	4
Leptomeningitis	6
Edema of the brain	4
Hydrocephalus internus	2
Multiple encephalomalacia	1

A good deal of work still remains to be done, but this much I think can be said to-day: That the brain is diseased in the majority, probably in all cases, of locomotor ataxy; that quite a number of the most constant symptoms of this disease are very probably, and some of them surely, not of spinal, but of cerebral origin; and that locomotor ataxy is certainly not merely a spinal disease, but one rather of the entire central and peripheral nervous system.

THE CAUSES AND TREATMENT OF MIGRAINE.[1]

BY H. GRADLE, M.D.,
OF CHICAGO.

A REVIEW of the latest standard text-books on nervous diseases reveals, on the whole, a very unsatisfactory state as regards the treatment of sick headache and shows also much uncertainty as to its causes. Marked discrepancies exist amongst different authors on the subject. On this account I wish to place before you some personal observations based on a large experience with this disease, as in my line of practice migraine is a very common annoyance.

In order to limit the subject I shall confine myself strictly to migraine or sick headache, or that form of headache which recurs in periodic attacks, with free intervals of variable length between the spells. This is the only definition which I can accept as characterizing the disease, because the symptoms may vary much in different persons. Even the symptom that has given the disease one of its names, viz., sick headache—that is to say, the nausea often leading to vomiting toward the end of the attack—occurs in less than one-half of the patients and in these not with every attack.

I have but little to add to the symptomatology. Some of the less common symptoms, however, may be worth pointing out. In one of my patients the attack began with dizziness and a subjective feeling of chilliness and numbness so pronounced that the disease was mistaken for malaria by the family physician. Yet this was a migraine of distinct ocular origin and completely relieved by glasses. In many cases an attack begins with flickering and greater or less visual disturbance, sometimes in the form of hemianopsia, sometimes with gradual shrinkage of the visual field. This form has been called by different writers ophthalmic migraine and scotoma scintillans fugax. There exist, however, all gradations between the most pronounced instances of this type and ordinary migraine. After the short spell of dizziness the typical headache comes on. It has almost seemed to me as if this form of "blind headache," as it is popularly called, were better known to the public than to the profession at large. In comparatively few instances the "blind spell" is not followed by any headache at all, its place being taken by other nervous symptoms, such as numbness or a feeling of pressure in the head.

In the etiology of migraine I wish to combat what seem to me certain errors that are repeated in most modern text-books.

Gowers, for instance, considers migraine a manifestation of gout. Its appearance, however, in early life, even in childhood, and its frequent spontaneous cessation after middle life, speak against this view. Even in migraine-patients of advanced age I have not seen gouty manifestations often enough to suggest any connection.

Again, many authors connect migraine with epilepsy. Yet the one is an exceedingly common complaint, the other a relatively rare disease. Moreover, it must not be overlooked that an epileptic may have sick headaches, as well as a person not so afflicted. The most probable reason why this otherwise unsupported view of the relation of these two diseases has been copied in the text-books seems to me to have been a diagnostic error. It is not unlikely that the minor attacks that often precede the history of pronounced epileptic seizures have been mistaken for erratic forms of migraine.

According to my personal experience migraine is not characteristic of a neurotic tendency. While I admit that this headache is often hereditary in families and that it is more liable to occur in persons of a neurotic disposition, I have observed many instances in which neither the patient's antecedents nor the family history indicated any liability to functional disorders or lesions of the nervous system.

The most frequent etiologic factor of migraine within my experience has been astigmatism. One of the reasons for dwelling on this relationship, so well known to all oculists, is the fact that it is slighted or ignored by many authorities on nervous diseases. (Gray, Gowers, Hirt.)

[1] Read before the Chicago Medical Society.

I cannot, however, give statistics of any value on this subject, for most of the patients came to me not on account of their headaches but on account of their eyes. Hence, even if I had complete records, they would consist of selected cases and would therefore be valueless for statistical purposes.

As an approximative estimate, I would judge nearly one-half of all instances of migraine to be dependent upon astigmatism. But the very fact that not all astigmatics suffer from sick headache shows that certain conditions of the nervous system are requisite to the occurrence of migraine.

The proof of the relation of astigmatism to migraine is furnished by the permanent cessation of the attacks when correcting glasses are worn. But the attacks do not always cease at once after the ametropia is corrected. Sometimes a few mild spells will still occur. Again, in other instances the attacks do not cease entirely, but become less frequent and less severe. It must be remembered, however, that the most perfect correction of the astigmatism ceases to be perfect when the patient looks through the glass at an angle with the axis of the glass, and that patients are not always as faithful about wearing their glasses as the physician expects them to be. Yet I could find on my records over a hundred illustrations of permanent relief by glasses, controlled by observation after months and years. Occasionally patients have returned to me after years of freedom, with a return of the old headache, due to incorrect repairs of their broken glasses.

The degree of astigmatism most commonly associated with sick headache is from one to three diopters. High degrees of astigmatism often cause no annoyance except poor sight. Whenever migraine seemed to depend on an error of less than one diopter down to one-half it has been mostly in persons of a neurotic history. I have never been able to trace sick headaches or any other form of complaint to an astigmatism of less than one-half a diopter. I have but rarely prescribed weaker glasses myself, but neither in my own instances nor in numerous observations in which patients had received such weak glasses from others have I seen any decisive benefit following their use. It has seemed to me that astigmatism with oblique meridians is more likely to cause migraine than when the principal meridians are either approximately vertical or horizontal.

Finally, I do not wish to conceal the fact that migraine may occur in conjunction with astigmatism, without apparent dependence upon the latter. For in a few rare instances the satisfactory optic correction had no effect upon the headache.

In practice the question often occurs whether migraine can be caused by an astigmatism which the patient does not feel as eye-strain. I have not made any observations enabling me to decide that question definitely. There are certainly instances in which patients with migraine curable by cylindric glasses do not complain of their eyes spontaneously, but on close questioning they have usually admitted that their eyes did get tired or weak on prolonged use.

Hypermetropia has been but rarely the cause of migraine in my observation. This condition, it is true, is a very common cause of headaches, but they are not of the periodic type. Very commonly hypermetropia, as well as astigmatism, gives rise to headache immediately following the use of the eyes, but this form of pain is not the subject of the present paper.

A much less common source of migraine in my experience has been nasal disease. Inflammatory affections of the nose and accessory sinuses lead very often to headache it is true, but not of the migraine type. Since Hack first reported his accidental cures of migraine by nasal cauterization some ten years ago, I have searched for the etiologic influence of nasal troubles in all cases which were not clearly traceable to eye-strain. I have not been able to confirm Hack's observations, however, that sick headaches are frequently ushered in by nasal irritability, and in such instances permanently stopped by cauterization of the turbinated bodies. But I have seen at least six instances in which unilateral migraine occurred principally or exclusively on the side of a nasal stenosis, and in which permanent improvement not far from a perfect cure followed the operative removal of the stenosis.

Another peripheral affection that has seemed to me to have an etiologic relation to migraine is intestinal catarrh. I cannot say much as to its frequency, on account of the limitation of my practice, but I have obtained not so very rarely a history of dyspeptic annoyances, with loose passages alternating with constipation, in patients whose migraine could be attributed neither to eye-strain nor to nasal disease. The relation of the two disorders to each other—suggested by the histories—was made very probable by the improvement in the headaches following the dietetic and hygienic management of the intestinal disease. As a rule, however, I have seen such patients in consultation and I have not always been able to follow their subsequent course.

In less than one-half of the cases of migraine under my observation no peripheral source of the headaches could be found.

An influence which has often shown itself by aggravation of the headaches is overwork and want of sleep, as for instance in nursing mothers. I have not been able to satisfy myself, however, that malnutrition from other causes plays any rôle in this disease.

It is of importance to study what influences lead to the occurrence of attacks in patients subject to migraine. Many persons claim that any disorder of digestion would bring on their spell. I think this is an error, and that the nausea which often terminates the attack is a symptom of nervous origin and does not indicate any primary gastric disturbance. In those instances which I have been able to study closest, I have never observed gastric anomalies preceding the attack; nor have I seen the attacks brought on by actual stomach-disorders. In some patients insufficient sleep is the most important exciting condition of migraine. In instances of migraine beginning with scotoma, I have observed attacks induced by dazzling illumination, an observation to which Manz has also called attention.

The treatment of sick headache has been most satisfactory to me in those cases in which eye-strain was the cause. With very few exceptions glasses have always given such patients relief. If well selected and properly worn they have practically abolished headaches in most instances.

My own experience, although limited, as well as the more extensive observations of Hack, suggest that whenever migraine cannot be attributed to eye-strain, a nasal influence should be searched for. Whenever a one-sided migraine corresponds to a one-sided nasal stenosis, or whenever a marked irritability of the nasal cavernous tissue exists and makes itself noticeable at the time of the attack, nasal treatment offers at least a reasonable prospect for a permanent cure.

The improvement which I have witnessed after dietetic management of intestinal catarrh should likewise be a hint in the examination and treatment of patients with migraine.

Whenever overwork seems to play a rôle, we may expect improvement by proper hygienic directions. I have repeatedly seen patients temporarily and a few times permanently benefited by travelling, even though the journeys did not involve complete relaxation from business or from studies.

Of drugs I know none that will cure migraine except cannabis indica. According to my experience from one-fourth to one-third of all patients are permanently benefited by its use. This applies equally to cases without a peripheral source of irritation, as well as to those with eye-strain, who for some reason or other would not wear glasses. Seguin, who first popularized the use of Indian hemp in this disorder, advised its continued administration in every case, and claimed more or less complete relief in about one-half of his observations after several months' treatment.

When I began the study of cannabis indica about twelve years ago many preparations in the market were inert. I found, however, a solid extract prepared by Hering absolutely reliable. Squibb's hemp is perhaps equally good, but I have not had the same experience with it. For reasons of convenience I have always used the tincture (360 grains to the pint) prepared with Hering's extract in doses of from 15 to 25 drops. This dose must not be given oftener than once in six or eight hours, or it will lead to a cumulative and often very disagreeable effect upon the mind. My first experience showed that in certain patients cannabis indica aborts each attack of migraine. If the first dose does not give complete relief I give another in six hours in slightly larger quantity. When moderate doses fail entirely, larger ones answer no better purpose. Very severe attacks are sometimes only relieved, but not entirely aborted.

Whenever hemp influences the individual attack, its continued use twice daily will usually protect the patients against the recurrence of the spells, and if persisted in for months, will cure many but not all of the cases. I have scarcely ever insisted on its continued use in those instances in which it did not alleviate the pain at the time, and have no reason to think that it would prove of service to such patients in the long run.

Other drugs recommended in the text-books for the cure of migraine, such as iron, strychnin, arsenic, and phosphid of zinc, I have used but little myself and invariably with negative results. But I have had a fair experience with patients who had followed such treatment on the advice of other physicians, and likewise without appreciable benefit.

If the individual attack does not yield to cannabis indica it can be stopped almost invariably by antipyrin. Acetanilid and phenacetin are not as universally successful as antipyrin. Guarana has in former times more often failed than proved satisfactory in my patients. Bromids do not stop the attacks, although they may relieve the discomfort. Chloral aborts migraine only when it induces sleep in patients whose headache will yield to sleep. Morphin has no effect at all upon the attack. It only dulls the pain while its action lasts.

Quack Medical Advertisements Refused.—Our gratification at finding the following prominent notice on the title-page of the *Farm Journal* leads us to quote it entire:

"No quack medical advertisements in this paper—not one. Yet dearly would they like to get in. This very month we could have had a thousand dollars' worth without the asking. And we call this simply 'fair play' to our readers. Would it be more than 'fair play' on *your* part to send us a club of five or ten subscribers in recognition of our efforts to keep our columns clear of such trash?

"Rogues shall not ply their trade at the expense of our subscribers, who are our friends, through the medium of these columns. Let this be understood by everybody now and henceforth."

TUMORS OF THE SUPERIOR MAXILLA.

By J. H. BRANHAM, M.D.,
OF BALTIMORE, MD.

The object of this paper is to relate the histories of two interesting cases operated on by me during the past summer at the City Hospital, and to discuss briefly some of the more important points suggested by these and similar cases, especially with reference to treatment.

Case I.—Peter K., twenty-nine years of age, a colored male laborer, was admitted to the City Hospital, June 22, 1893. Nine years previously the left half of the inferior maxilla was removed by the late Prof. O. J. Coskery for sarcoma; about three years ago an epulis was removed from his left superior maxilla by Prof. C. F. Bevan. The patient says that the present growth has been coming on for about two years. There is no history of injury. Examination showed considerable bulging forward of the left side of face and projection of the malar bone and part of the superior maxilla upward, so as to close, partially, the left eye. The left hard palate was very much depressed, and projecting backward behind the posterior palatine arch was a large, soft tumor which largely filled the left side of the pharynx. The clinical diagnosis of sarcoma of the superior maxilla was made, and excision was advised and readily consented to by the patient.

The operation was performed June 28, 1893. The face and neck having been shaved and made clean by soap, water, potassium permanganate, and mercuric chlorid, the patient was given chloroform and a preliminary tracheotomy was performed. The pharynx was cleansed and packed with absorbent cotton. The Ferguson incision from the front of the ear underneath the orbit and down the side of the nose where it joins the face, and down the middle of the lip, was then made. The hemorrhage was considerable, but was readily controlled by Péan forceps. The cheek was next separated from the bone. The bony attachments of the left superior maxilla were next rapidly cut through with large bone-pliers, and this bone with the left palate bone was removed. It was now found that the pterygoid processes of the sphenoid were involved in the growth which projected backward, and these were cut through high up at their junction, and removed. It was discovered that the tumor projected downward toward the glenoid cavity, and in removing this part the hemorrhage was excessive. As soon as the operation was completed the hemorrhage was easily controlled by pressure.

The posterior attachments of the tumor were separated by scissors and the curet was applied to the deeper parts of the cavity after the operation. The cavity was now packed with sterilized gauze, and the skin-wound was closed by continuous sutures, after which a sterilized gauze dressing was applied.

The tracheotomy-tube was removed on the second day, but the wound remained open for about a week. The packing was removed from the cavity on the seventh day. The foul odor which is so disagreeable in these cases was overcome to a great extent by a 2 per cent. solution of potassium permanganate.

The temperature was never higher than 102°. The skin-wound healed by first intention, the lower cavity left by the operation rapidly filled by granulation, and the patient made an uninterrupted recovery. He was discharged July 28th entirely well and strong.

Case II.—Hannah McK., a white female, forty years of age, American, widow, was admitted to the City Hospital, August 26, 1893. She had been struck on the side of the head by a shuttle about a year before. About four months ago she first noticed a swelling on the right side of the face, which seven weeks ago broke into the nose and mouth and discharged very offensive matter. This discharge has been repeated every two or three days since. The patient has suffered great pain and has been using anodynes freely. She was very anemic and weak. Projecting from the right maxilla underneath the skin, by the cheek, was a soft, pulsating tumor that almost closed the right eye; over this, the skin was tense and reddish. The mass pressed well down into the mouth and closed the right side of the nose.

Operation was undertaken August 28, 1893. The incision was the same as in the preceding case. The tumor was found to have destroyed almost entirely the superior maxilla. This, with the palate and part of the ethmoid were removed, and the cavity was throughly curetted. The posterior part of the orbit was extensively invaded. The patient took the anesthetic (chloroform) badly, and was given several injections of strychnin and digitalis during the operation. She rallied slowly after the operation and was very weak for several days. The hemorrhage, although not excessive, was severe. The skin-wound healed by first intention. The woman improved rapidly after the first few days, and was able to be about in two weeks, but complained of great pain in the eye, for which reason she was kept in the hospital.

The pain in the right eye and the swelling of the lid remained, and were troublesome.

September 20th the pain in the eye had increased so as to require anodynes. During the last part of October the patient became irritable, and then comatose, and finally died on November 1st, two months and three days after the operation.

It was impossible to secure a post-mortem examination, but death undoubtedly resulted from extension of the disease to the cranial cavity. These tumors were kindly examined by Prof. Kierle, and are both spindle-celled sarcoma.

Butlin[1] says that the larger number of malignant tumors of the upper jaw appear to be carcinoma, usually squamous; while Joseph D. Bryant[2] in the histories of 250 cases gives 71 as sarcomatous to 47

[1] The Operative Treatment of Malignant Disease. London, 1887, p. 128.

[2] Transactions of the Medical Society of the State of New York, 1890, p. 63.

carcinomatous. This would indicate that sarcoma occurs more frequently, the giant-cell variety being the most common.

The early diagnosis and treatment of these tumors are of the greatest importance, as thorough removal in the first stages gives the only hope for these poor sufferers. Partial excision is comparatively a safe operation, but is likely to be followed by recurrence, and should be employed only when the tumor cannot be entirely removed, and even when complete removal is practised the patient should be carefully watched for recurrence.

The complete removal of the superior maxilla has, according to Butlin, a mortality of 30 per cent. This conclusion is reached from a study of 108 cases —42 from the various London hospitals and 66 from German reports. Bryant (*loc. cit.*) reports 183 cases with 26 deaths, or 15.5 per cent. The sources of his statistics are not given, but they are up to a date three years later than Butlin's, and probably contain many American cases.

The question of preliminary tracheotomy is very important. It enables the operator to select the most convenient position for the patient, and undoubtedly increases the ease with which the tumor can be studied and manipulated. On the other hand, the operation of tracheotomy in itself adds something to the danger, and I think it probably increases the liability to septic pneumonia, from the passage of substances from the pharynx into the bronchi. This would naturally be the case, as ability to expel such foreign bodies by coughing is lost.

The operation is naturally accompanied by severe hemorrhage, which, in a considerable number of cases, ends fatally. This is met and limited by rapid operation, and pressure, direct or to the carotids. Some operators recommend the ligation of the common or of the external carotids as a preliminary step. As the ligation of the common carotids has a mortality at least as great as the removal of the bone without it, the procedure is not likely to have many advocates, and probably will be performed but seldom in the future. On the other hand, the ligation of both external carotids is comparatively safe, and facilitates the ease with which the operation can be completed. Bryant also claims that it decreases the growth of tumors to a great extent, and probably retards the tendency to return after removal. From these considerations I believe it to be commendable, and shall in future employ it in every vascular and rapid-growing tumor.

The first case presented by me is of especial interest, because of the occurrence of sarcoma in both maxillæ on the same side, with an interval of about nine years. From the fact that the tumor removed by me was closely attached by a dense pedicle near the glenoid cavity, it seems possible that recurrence took place in the periosteum around the end of the removed bone, and the growth afterward extended to the upper maxilla, illustrating the fact that these tumors tend to recur in the periosteum of the bone when they primarily spring from that tissue.

The second case represents the great rapidity of growth of some of the sarcomata. It was first noticed about four months before removal, and six months before death from extension to the cranial cavity.

The most disappointing feature about these cases is the great frequency of recurrence. Few cases escape this, but with the better understanding of the dangers of these tumors by the laity, as well as by the profession at large, I believe that in the future earlier operations will be done and more permanent cures will result.

Before closing, I wish to refer to one very remarkable operation reported by Mr. Earle, who, in 1831, removed the right superior maxilla for fungoid growth. The common carotid was first tied, and the night after the operation the patient was bled a pint! In spite of this the patient is reported to have recovered. In connection with this I will borrow a quotation from Bryant:

> "Man yields to custom as he bows to fate,
> In all things ruled, mind, body, and estate;
> In pain and sickness, we for cure apply
> To those we know not, and we know not why."

These lines were written by Crabbe one year afterward, and it is barely possible he had heard of this remarkable case treated by this surgical Sangrado.

CLINICAL LECTURE.

TALIPES PLANUS; SUSPECTED FRACTURE OF HUMERUS; FIBRO-LIPOMA; DRESSING OF EMPYEMA AFTER ESTLANDER'S OPERATION.[1]

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

THIS patient is a lad of nineteen, who has a variety of club-foot known as "flat-foot" or "splay-foot"—more technically, as talipes planus. There is also the tendency for the foot to rest upon its inner border, known as talipes valgus. I have here the foot and leg of a skeleton, showing that the normal foot contains a bony arch, the weight of the body resting on the heel, the outer side of the foot, the ball of the foot at the extremity of the metatarsus, and the toes. In the condition of talipes plano-valgus, both the antero-posterior and the lateral arches are flattened out and the whole surface of the sole comes on the ground. But this is not all. I find here a positive change in the shape of the tarsal bones, of just how many I do not know, but the astragalus, which in the normal foot never protrudes in any

[1] A clinical lecture delivered at the Buffalo General Hospital.

direction, bulges out beyond the external malleolus, while there is a corresponding depression on the inner side of the foot. There is, however, no true luxation of any of the tarsal bones.

This condition began when the boy was old enough to work on a farm. In spite of his youth he is as large as most adults, and his tarsal bones and ligaments, which were doubtless strong enough to bear a weight of a hundred pounds, have yielded under a weight of a hundred and fifty pounds. If the patient could have led an easy life, probably this condition would not have arisen, but he is a poor Swedish boy who has had to do a man's work. Some of you might be inclined to ask what harm the flattening of the foot does and whether it is not to be regarded rather as a personal deformity, of little consequence to one who has not the opportunity to participate in social life. In reply I might call your attention to the improbability of a boy in his position seeking relief for purely cosmetic reasons. As a matter of fact, flat-foot is not usually painful unless it is subjected to much strain from the person's being continually on his feet. Any joint or series of joints that have to work in an improper position are strained in parts where there is no natural provision or protection against strain, and so this very condition has received the name talipes planus *dolorosus*. I can put this young man to bed and make him perfectly comfortable, but he will suffer as soon as he gets up and puts his weight on his feet. I can relieve him by dressing his feet in plaster-of-Paris, so as to give them an external support, but this treatment would have to be kept up for six months or more. It might be seen that the arch of the foot could be restored by building up the middle of the sole of the shoe, but there are objections to this method of relief.

You will notice that by twisting the foot inward I can restore the arch and make the outer side the lower, as it should be. In a child, I could probably restore the foot to its normal shape simply by holding it in this position by plaster-of-Paris for a long time. It has been suggested to hold the foot in this position for a little while and then to apply the actual cautery to the inner side of the foot and the sole, in a series of linear stripes, going down to the tendon-sheaths. The cicatricial contraction which results will shrink the plantar fascia so as to hold the arch of the tarsus in place. This method is available in moderate degrees of flat-foot, especially in young children, but it requires a long time before the cicatricial tissue is firm enough to be put to the test of actual use. In an adult, and this lad has almost attained his growth, I prefer to give an anesthetic, and, applying an Esmarch bandage so as to make the operation bloodless, to remove a wedge-shaped mass from the tarsus, mainly from the astragalus, and bring the parts together with strong sutures. In order that the result of the treatment may be plainly shown, I have had two plaster casts made of the feet in their present state of deformity. No weight rested on the feet while the casts were being taken, so that the deformity is not seen at its worst.

The feet have been cleaned and rendered much whiter than I thought possible by prolonged treatment with hot water and liquor potassæ. After washing the foot again with bichlorid of mercury solution, the Esmarch bandage is applied so as to strip the blood up toward the knee and the tourniquet secured. The incision is made longitudinally over the prominence of the astragalus. The bone is chiselled away and the parts brought together so as to close the gap in the tarsus. You can see that the arch is now quite well restored; the fascia and superficial structures are united by one set of heavy catgut sutures; the wound is dusted with iodoform, the surrounding area anointed with sterilized vaselin and dressed with bichlorid gauze and naphthalin cotton. The operation is repeated on the opposite foot. Now, in order to prevent all disturbance of the feet, I will surround the antiseptic dressing with a plaster cast applied in the usual manner.

Some of you may have read in the papers of a little Polish girl who had been cruelly beaten and starved by her father, and who was rescued by the Humane Society. This is the little sufferer, who was brought to the hospital a few days ago with her right arm so badly swollen that, even under chloroform, a careful examination was impossible. There is still a great deal of swelling—not so much at the elbow as above. The only safe course in diagnosticating fractures is to compare opposite limbs. At the elbow the three prominent landmarks are the condyles of the humerus and the olecranon, which should be in the same horizontal plane with the arm flexed at a right angle. By comparing the two sides, even a slight disturbance of the normal relations of these three prominences may be detected. In this case they seem to be in the same relative position on each side. Complete extension of the arm causes no pain, and it is only when flexion is carried beyond a right angle that complaint is elicited. Although fracture has been suspected, we must remember that the pain may be due to a sprain, to cellulitis, or to other inflammation about the joint. At various places you can see where ecchymoses are fading away into a greenish-yellow discoloration. It is now a week since the patient was brought to the hospital, and although I cannot say absolutely that there has been no fracture, I can say that the parts are at present in their normal position, and there is nothing to do but leave the arm at rest, applying an absorbent ointment of ichthyol and blue ointment diluted with lanolin. A splint has been kept on as a precautionary measure. I see no further indication for anything more than a triangular splint to keep the parts at rest.

A year ago we had a patient in the hospital from whose arm I removed a pedunculated lipoma as large as his head. He has shown his appreciation by sending in another patient, with the message that "out in his part of the country there are lots of men with bunches, and he is going to send every one of them here." The present patient is a middle-aged laborer, with a tumor at the back of his neck. It has grown slowly for years; it is painless, and gives him no trouble except the inconvenience of preventing him from wearing a shirt and collar in the ordinary way. It is somewhat soft, and without being actually fluctuating, it is movable in the deeper tissues and the skin is movable over it. It is undoubtedly benign and probably is composed of fat. Now that the patient is entirely relaxed by the anesthetic, it seems more elastic, as if there were fluid confined in a sac or, on the contrary, a more consistent mass than the ordinary lipoma. I expose it by an incision about fifteen

centimeters long and find a solid tumor. There are no important vessels or nerves to avoid, and I can proceed rapidly with the enucleation. You see it is quite nodular, some parts being almost separated from the main tumor. A few vessels require ligation. The raw surfaces are brought together by buried sutures, to check the capillary oozing and get more speedy union. The ordinary antiseptic dressing is applied, and over it a large flat posterior splint, which I have had made to fit the trunk and neck, so as to immobilize the parts. This will be of special service during the restless stage which follows the anesthesia. The wound ought to be healed in a week. On cutting into the tumor, I find an intermixture of fat with quite dense fibrous tissue, so that the growth is properly a fibro-lipoma.

This patient is the one on whom I performed Estlander's operation a few weeks ago. He has been reserved until the close of the clinic because I did not wish to run any risk of infecting other patients with the foul pus which still exudes from the remains of the pleural cavity. You will notice that the dressings are stained green. This is due to the presence of a particular bacterium—the so-called bacillus of green pus—which always indicates a slow and chronic suppuration. The patient, at the time of operation, was in quite a critical condition, and there was a fistula through which pus was constantly overflowing. A free incision was made, and on lifting up the flap containing the resected portions of several ribs I could plainly see the motion of the heart inside the pericardium, which was covered with granulations. Already there has been a marked collapse of the chest-wall to meet the lung, which could not expand to meet the thorax wall. The patient is in better spirits since the operation, and he will be, I hope, a healthy man, if not a symmetrical one. Some of you were doubtless surprised to see me remove so much tissue. Yet, at the operation I was hurried so much by the critical condition of the patient that I could not take time to remove all that I wished. Here is a space that will have to fill up with granulation-tissue, because the strength of the patient did not permit the resection of another rib. This operation was thought out first on theoretical grounds, and Estlander had the hardihood to carry it out in practice and show that, desperate as it was, it was nevertheless practicable. Many years ago, when I was a hospital interne, I saw a number of cases of empyema go steadily downward from the exhaustion of hectic fever, without relief. Drainage was made use of, but it was not sufficient in the worst cases. Out of ten operations which I have performed in this hospital, only one patient has died from the effects of operation, and that was a desperate case which had been sent to Buffalo to die. In several cases the openings have been larger than in this case.

The cavity is freely irrigated with a boric-acid solution and the dressing completely renewed. Under the pus you can see healthy granulations springing up.

Pfarrer Kneipp and His Water-cure.—It is reported that the so-called priest-physician of Bavaria has been called to Rome to advise Pope Leo on matters of health. The "Wunder-doktor" has advised cold bathing, and has predicted for his Holiness "several more years of life." It is said that the now-aged Pfarrer receives "over several hundred patients" daily.

CLINICAL MEMORANDA.

THREE CASES OF PNEUMONIA FOLLOWED BY MANIA.[1]

BY J. B. CAMPBELL, M.D.,
OF LONDON, CANADA.

CASE I.—In the spring of 1874 I was called to see a young man, twenty years of age, who had been ill for over a week with pneumonia.

He was treated by a neighboring physician who reported favorably concerning the case from day to day, and finally about the seventh day pronounced him out of danger. About twenty-four hours later the physician was again summoned in great haste, and on his arrival he found that the patient after sleeping soundly awoke in a wild delirium. The physician ordered food and stimulants, but on his return in the evening there was no improvement. The next morning, the man being still wild and maniacal, I was called in and found that he was required to be held in bed.

On examination I found the patient with a fast pulse, cold and perspiring skin, pallid face, and lungs clear or nearly so.

I advised the treatment, which consisted of brandy and milk, with a mixture of ammonia and camphor, to be continued. The patient died during the night. The physician informed me that he had thought the case one of ordinary right-sided pneumonia, and he could not account for the sudden change and delirium after he had about given up the case as cured.

CASE II.—On February 14, 1880, I was called to see a young man of about sixteen years of age, who on the evening before, and about fifteen hours before I saw him, was taken with a chill. I found him with face flushed, perspiring, the pulse full and strong (120 per minute), and with a temperature of 105°. He complained of pain in the right side and his breathing was short and quick; rusty sputa, hacking cough, dulness of the lower lobe of the right lung and crepitation in the upper lobe were present. The left lung was normal or nearly so. I ordered a hot bran-poultice, which was on the chest, to be continued, and prescribed the following:

R.—Liq. ammon. acetat. . . . . ℥j.
Spt. æther. nit. . . . . ℥iv.
Tinct. aconit. . . . . gtt. x.
Aquæ . . . . . ad ℥vj.
Sig.—A teaspoonful every hour.

On February 15th the pulse was 110, the temperature 104°, the cough free, and the sputa considerably tinged with blood. There was no delirium, except for a few moments after waking from sleep. On February 16th, 17th, and 18th the case seemed to progress favorably. On the 19th the temperature was 102.5°, the patient was a good deal better, the expectoration was free, and the cough was nearly gone. I changed the medicine and gave:

R.—Ammonii carb. . . . . gr. ij.
Ext. scillæ et senegæ . . . gtt. j.
Syr. simplicis . . . . . ℥j.

[1] Read before the London Medical Society.

every three hours. I felt well pleased with the progress the case was making, and the family did also; all agreed that the patient was getting on better than a brother did whom I treated for the same disease a year previously. On February 20th the temperature was normal, the appetite was returning, and the patient felt nearly well. I discontinued the poultice, and wrapped the chest in cotton batting, with a bandage. I ordered the last mixture continued, with milk, beef-tea, etc. On February 21st I was summoned early in the morning and was told that the patient awoke from sleep, became delirious, and was wild most of the night, the nurse being unable to keep him in bed. I hurried to him and found him sitting up in bed and pulling the bedclothes. He appeared to be afraid of those about him; his face was pale, with a maniacal expression, his pulse was fast, he had no cough, his lung was nearly clear, his temperature subnormal, his skin cold and bathed with perspiration. He appeared to recognize me when I spoke to him and quieted himself. I covered him well with blankets and ordered hot bottles in the bed; I gave spts. ammoniæ aromat., digitalis, and brandy, and left. I was again sent for in the evening, and on arrival I found him worse than in the morning, although his mother told me that at times during the day he was rational; the pulse was now weak and irregular. He was afraid and saw soldiers coming to take him away, and also had hallucinations of hearing. He fought, pleaded, and wept, till finally he threw himself across the bed exhausted, sobbed a few minutes, and then died, about thirty hours from the advent of the mania.

The loss of my patient caused me a great deal of worry. The family had unbounded confidence in my skill and ability, as well as in my honesty. The manner, however, in which I reported progress from day to day till the last, when it was apparent to all that there was no hope, caused the family and friends to censure me very much; some of them thought I must have known better, while others attributed my actions to ignorance. This case brought back to my mind the first case reported, when the other physician had to bear the blame and censure of the friends.

Case III.—On April 10, 1890, I was called to see a farmer's son, fifteen years of age, whose mother informed me that he had been sick for nearly a week; he was taken with a chill while working in the woods, and had had cough and fever since. This morning she noticed rusty-colored sputa and sent for me. I found the temperature 104.5°, the pulse 125, and respiration 60; the face was flushed and dusky, the tongue coated and moist; there was pain in the right side, with hacking cough, crepitation in the lung, from base to apex. The left lung was nearly normal.

I prescribed a mixture of liq. ammon. acetat., spts. æth. nitros., and aconite, to be given every hour, and ordered a linseed-poultice with mustard to the chest. On April 11th in the morning, the pulse and temperature were still about the same, the respiration 55, and perspiration was free. He did not rest well the night before, but complained of the pain. I left a powder containing quinin, gr. iij, Dover's powder, gr. v, to be given at night, and advised the other treatment to be continued. On April 12th the patient slept better, and did not have much pain, but was somewhat delirious; there was no change in temperature or pulse. The respiration was about 50. On April 13th and 14th the symptoms were about the same. On April 15th, when I entered the room, the sight of my patient sent chills over me, as the memory of the second case reported was brought to my mind. The expression of the face was exactly the same—it was pale and perspiring; the temperature was 94°, the pulse 60, and respiration 16. The patient was delirious during the night and the nurse had to hold him in bed. The delirium came on after waking from a "quiet and nice sleep," I was informed; he had rational intervals, but required to be held most of the time.

I prescribed the following:

R.—Tr. digitalis . . . . . jss.
Ammon. carb. . . . . ʒij.
Spt. frumenti . . . . . ʒiv.
Sig.—ʒij to be given every hour.

I ordered hot water to his feet and that he be wrapped in warm blankets. On April 16th the temperature was 97.5°, pulse 70, mind rational, and appetite better. On April 17th the temperature was normal. I dismissed the case, which made a good recovery.

I never could satisfy myself as to the cause of the sudden maniacal delirium coming on after the fever was all gone. I read all the text-books on practice that I could get (some dozen or more) and I found in none of them anything that enlightened me on the cases. The only solution of the question I find is in works on insanity—for example, that of Griesinger, who gives an account of insanity following pneumonia and other febrile diseases. Blandford also reports cases and cites Weber on the subject in the *Medico-Chirurgical Transactions*, vol. xlviii. Dr. Clouston in his Morisonian Lectures, 1875, also gives particulars of ten cases of "post-febrile insanity."

The common features that strike one in these three cases are the youth of the patients, the appearance of the mania after a sound sleep, its short duration, and the fact that in all three the pneumonia was right-sided. They were all of neurotic families. The fatal termination of two of the cases by exhaustion would indicate the necessity of procuring sleep or rest at all hazards.

Were I to encounter a similar case, I should not hesitate to administer opium along with my former treatment.

TWO CASES OF FUNCTIONAL NERVOUS DISEASE TREATED BY TENOTOMY OF THE SUPERIOR AND INFERIOR RECTUS MUSCLES.

By HOWARD F. HANSELL, M.D.,
of Philadelphia, Pa.

The following cases demonstrate, individually, the rôle played by a want of equilibrium in the ocular muscles, demanding constant and unconscious effort to maintain single and clear vision, in producing disturbances of the nervous system, simulating organic disease, and the marked amelioration of the symptoms following restoration of the equilibrium.

The conservative physician demands proof, or at least undisputed evidence of the trustworthiness of new therapeutic agents, before adopting the suggested line of treatment and risking his patient's health and his own

reputation by displacing older, well grounded, and authenticated methods, although perhaps unsatisfactory.

Current ophthalmic literature seems to indicate a more general belief in the theory, advanced by Stevens, of the causative relation of anomalies of the ocular muscles to functional disease of the nervous system, than prevailed for some years after the publication of his Belgian Prize Essay and his series of articles in the *Archives of Ophthalmology*, at least in so far that opportunities for personal investigation are availed of after therapeutic efforts in other directions have proven unsuccessful.

The subject is attractive to both ophthalmologist and neurologist—to the former, in widening his limited field of practice, and to the latter in suggesting for his consideration a means of cure, in properly selected cases which have not yielded to his other therapeutic resources.

I am indebted to my friend Dr. K. C. McWilliams, of Philadelphia, for the opportunity to see in consultation and to present to the attention and judgment of the profession the two cases described herewith. I have endeavored to limit the clinical histories to a bare statement of facts and have purposely omitted comments.

Case I.—Miss R., aged sixteen, a school-girl, of good family history, with no inherited neurotic tendencies, consulted Dr. McWilliams in May, 1893, on account of epilepsy. Her mother related that the first seizure was excited by the horror of seeing a brother drown two years before. The attacks have very gradually increased in frequency until the present, when they recur

Fig. 1.

Miss R., one week before operation.

three and four times in the week. Without warning, she becomes unconscious, falls if standing, has a slight general muscular spasm or convulsion, recovers after a few seconds, and eructates large quantities of gas. She complains also of severe headache and vertigo after an hour's close application to her books. She makes no mention of the facial spasm conspicuously shown in the photograph. In spite of treatment directed to both the nervous system and the eyes, by various specialists, during the past two years her symptoms have increased in severity. Refraction under atropin = + 0.75s.= 6/6, O.U. Left hyperphoria $2^{\circ} - 3^{\circ}$. Lateral muscular action inconstant; at times esophoria, more frequently exophoria. Occasional diplopia. No lesion of media or fundus.

Prisms to correct the hyperphoria were worn for one week with great benefit. On June 20th, tenotomy of the left superior rectus was practised and the muscular equilibrium established.

The relief to the epilepsy, headache, and vertigo was immediate and absolute, and to this date (February 6, 1894) has continued.

Fig. 2.

Miss R., a few days after operation.

Case II.—Miss O., aged nineteen, a weaver, without inherited diathesis, consulted Dr. McWilliams, October 13, 1893, complaining of severe asthenopia of six months' duration. Attempts to use the eyes for close work were attended with pain in the head and eyes and frequently with nausea, vertigo, and loss of conciousness, without general muscular spasms. In the absence of known organic disease and from the close connection of the periods of unconsciousness with use of the eyes at the near-point, the girl properly concluded that the source of her trouble must be in a derangement of the ocular apparatus. She had not placed herself under medical treatment during the preceding six months, but had consulted two ophthalmic surgeons and had worn various spherical lenses without benefit. The diplopia has recently become a nearly constant symptom. Left hyperphoria = 4°. Exophoria alternating with esophoria at 6 m. Exophoria in accommodation. Refraction under atropin = 1D = 6/6, O.U. No lesion of media or fundus was present. Prisms correcting the hyperphoria were worn with comfort for seven days. October 29th, tenotomy of the left superior and right inferior rectus gave perfect binocular fixation.

Miss O. has been relieved of headache, vertigo, and fainting attacks and has been able to resume her occupation. She still has some asthenopia in reading.

These cases demonstrate the necessity for including an examination of the ocular apparatus in determining the cause of functional disease of the nervous system.

A CASE OF PRIMARY CARCINOMA OF THE BODY OF A DIVIDED UTERUS.

By CHARLES B. PENROSE, M.D.,
Professor of Gynecology in the University of Pennsylvania, Philadelphia.

The following case of primary carcinoma of the body of a divided uterus possesses enough points of pathologic interest to merit report:

M. L., a white woman, forty-nine years old, was admitted to the hospital of the University of Pennsylvania in September, 1893. Menstruation had begun in her sixteenth year and had always been irregular, occurring every two, three, or four weeks. The bleeding had

always been excessive and had continued from one to three weeks. There had been no dysmenorrhea. The last menstrual period had occurred five months before admission to the hospital.

For about one year before admission she had suffered with pain in the hypogastric and sacral regions, increasing vesical and rectal tenesmus, and increasing loss of strength and weight. There had been no leukorrhea. She was unmarried and had never been pregnant. Her appearance upon admission was anemic. The skin was sallow; there was general emaciation. The temperature was 100°, the pulse 138.

Examination showed normal external genitals. The ostium vaginæ was normal in size. The vagina was divided into lateral halves by a fleshy septum in the median line, extending from a half-inch above the ostium to the uterus. Into each half of the vagina projected a cervix uteri of normal size and shape. A hard polyp—about a half-inch in diameter—protruded from the os of the right cervix. The uterus was irregular in shape, nodular, much increased in size, and adherent.

The history of the case—the irregular profuse bleeding from the uterus, the delayed menopause, the pelvic pain and tenesmus, and the emaciated and sallow appearance occurring at the menopause—suggested the diagnosis of uterine fibroid which had undergone sarcomatous degeneration. The physical examination revealing a hard uterine polyp and an enlarged nodular uterus, increased the probability of this diagnosis.

Exploratory celiotomy was performed two weeks after admission. The radical operation was found to be impossible, as the uterus was adherent to the sigmoid and other pelvic structures by extension of the tumor. Eight or ten inches of the sigmoid flexure and the descending colon were involved. After recovery from this operation the woman left the hospital, and died of exhaustion two months later. The uterus, vagina, and vulva were removed post-mortem, and were submitted to pathologic examination by Dr. Beyer.

Pathologic Report.—Growing from and infiltrating the uterine body is a tumor the size of a cocoanut. The cervices are equal and well-developed, of normal size, and patent. From the right cervical canal grows a mucous polyp about the size of a hickory-nut. The uterus is divided into two lateral parts by a septum extending to within a half-inch of the fundus. The uterine cavities are about the same size, and of the normal length. The vaginæ are well-formed, of equal size, admitting easily two fingers. The septum extends to within a half-inch of the ostium vaginæ; below this there is, posteriorly and anteriorly, a partial septum. The vaginal walls are three-quarters of an inch in thickness and carcinomatous infiltration can be detected to within an inch of the vulva. The base of the bladder is infiltrated by carcinoma. Microscopic sections from the uterine bodies and the cervices show complete, and from the posterior bladder and vaginal walls partial, carcinomatous infiltration. The carcinoma has evidently originated in the body of the uterus and has secondarily involved the cervices, bladder, and vaginal wall.

The fact that the microscope showed that the vaginal walls were infiltrated with carcinomatous tissue to within one inch of the vulva is of great interest from the operative point of view. It shows the impossibility in any case of malignant disease of ascertaining with the eye or finger, at the time of operation, the extent to which the disease had infiltrated. At the time of the exploratory operation, two months before death, the vagina and vaginal cervices appeared perfectly healthy, and yet the microscope would probably have shown beginning carcinomatous change. It is probable that many cases of so-called recurrence after hysterectomy for malignant disease are really cases of continuation of a pathologic process which had been unrecognized at the operation.

THERAPEUTIC NOTE.

A CASE OF PAROXYSMAL TACHYCARDIA, OF LONG STANDING, RELIEVED BY THE USE OF BEECHWOOD CREOSOTE.

By W. T. S. CORNETT, M.D.,
of Madison, Indiana.

It is proper to state that the writer is both physician and patient in the case to be described. The patient is an octogenarian, and for the last forty years has been more or less subject to chronic rheumatism. Twenty years ago, after taking unaccustomed exercise on foot for several days in succession, I became much fatigued, and, as a consequence, the rheumatism was aggravated. Shortly after this increase of rheumatism, obscure disease set in, difficult to diagnosticate, but which, on further observation and study, proved to be endocarditis. This attack occurred late in the fall, and I was confined to bed most of the time all winter with a low grade of fever, and with persistent insomnia. I was not conscious of having slept at any time during the winter, yet there must have been unnoticed sleep. No hypnotics were used. There was one paroxysm of pseudo angina pectoris during the winter, which was promptly relieved by swallowing a spoonful of ether that happened to be at hand. When spring came, the febrile condition subsided, and sleep returned, and outdoor exercise was also resumed.

There are members of the profession who think that rheumatic endocarditis occurs only in the acute form of the disease, but there is high authority for saying that it also occurs in the chronic form. Endocarditis seldom proves fatal, but those who are so unfortunate as to have had it seldom, if ever, completely recover from its consequences. Paroxysmal tachycardia is the result in the case under consideration. Shortly after recovery from the endocarditis, I would awake at night, finding myself too hot, and the pulse up to 120 or 130 per minute, making the impression on my mind that I was having an attack of fever that would confine me to bed; but to my surprise, when morning came, the pulse would be down to 70, and the sense of heat gone. These paroxysms did not occur every night, or every other night, or at any particular hour of the night, but always at unexpected times. After a time, they commenced occurring in the daytime, often many of them per diem, and most of them of short duration. These paroxysms were unaccompanied by pain, but I could always tell when they occurred by a sense of commotion at the heart. Then placing the finger upon the pulse, and holding it there a sufficient length of time, it would be found to drop sud-

denly from 120 or 130 to normal (70). This is a paroxysm of tachycardia, of sudden and unexpected onset, and with sudden termination at an uncertain period. I was thus afflicted for twenty years, when a bronchial trouble occurred, with a glutinous expectoration, very difficult to eject from the throat. For this bronchial trouble it was determined to test beechwood creosote as a remedy. Under its use for a week or ten days the expectoration was relieved, the cough mitigated, and, to my surprise and gratification, the paroxysmal tachycardia had disappeared. The sudden cessation of this long-standing motor affection of the heart can be attributed to nothing but the action of the creosote. I had for a long time believed that these paroxysms were caused by aortic regurgitation from valvular insufficiency, causing the heart to struggle for the relief of the distended ventricle; this being accomplished, the pulse would suddenly fall to normal. The action of the creosote in this case showed conclusively that the tachycardia was not caused by valvular insufficiency, but was purely functional. Post-mortem examinations in other cases have shown that the affection under consideration can, and does, have an existence when there is no structural disease of the heart. Dr. G. W. Jacoby read a paper some time ago before the Academy of Medicine in New York, in which he says that paroxysmal tachycardia is a disease of adult life, the etiology being obscure. "The best-established causes are bodily and cerebral overwork. In these cases, it seems probable that the condition is a bulbar neurosis." Dr. Herter referred to a case in a man who suffered from intestinal indigestion, and suggested that the mechanical distention of the colon and other portions of the intestines, as well as the poisonous products of indigestion taken into the blood, may act as a cause of the paroxysms.

Under the use of creosote three times per day I have now had exemption for more than seven months, with the exception of a few slight returns when the medicine has been neglected. Cure, in the proper sense of that term, is not claimed in this case, but exemption is being purchased at so cheap a rate that it is nearly equivalent to cure. The relief is very great indeed.

The question now arises as to the *modus operandi* of creosote in the case under consideration. It is admitted that an answer completely satisfactory to this question cannot now be given. The heart, after the attack of endocarditis, has been left in an irritable condition, from which complete recovery is perhaps impossible, especially in one of advanced age. Creosote is a tonic, and the most reliable intestinal disinfectant of which I know. It prevents fermentation in the stomach and intestines, and thus there are no poisonous products to be absorbed and taken into the blood, and there is high authority for saying that it combines with and renders innocuous poisonous products that reach the blood from other sources. "It is interesting to note that quite recent researches indicate that the good effects of the creosote, or guaiacol treatment of pulmonary tuberculosis, are due neither to the colyseptic (or development-hindering) properties of guaiacol, as some authors, including Guttmann, the originator of the treatment, believe, nor purely to its stomachic and tonic virtues (as others have asserted), but to the fact that it forms compounds, eliminable from the blood in a dissolved state, with the toxic albuminous by-products of the activity of the tubercle-bacillus. (Hoelscher and Seifert.) It is to these albuminoids that the fever, night-sweats, and disturbances of appetite, digestion, and general well-being must be ascribed, and with their removal or conversion into inert compounds, all these symptoms disappear." (See Helbing's *Modern Materia Medica*, 1893.) Creosote lessens the irritability of the bronchial tubes, and thus frequently relieves cough. Two-thirds of the creosote that enters the blood is eliminated by the kidneys, and the lining membrane of the heart is constantly being bathed with blood holding the medicine in solution as long as the treatment is continued.

There are several grades of creosote to be found in the shops, made from coal-tar. These should never be used as medicines. Creosote made from beechwood tar, and with a reliable brand, should always be prescribed. The dose in the case under consideration was one drop three times a day, after eating, and now, at the end of seven months, has not exceeded two drops three times a day.

NEW DEVICE.

AN AXONOMETER.

By JAMES THORINGTON, M.D.,
INSTRUCTOR IN DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

In making use of the shadow-test as a ready and rapid method of estimating errors of refraction, the direction of the principal meridians of corneal curvature are often difficult to determine, and the statement of the patient must be accepted when confirming the correction, or if there is still uncertainty, the ophthalmometer of Javal must be brought into use.

At my suggestion, Messrs. Bonschur & Holmes, of this city, have constructed a very simple instrument, which, for want of a better name, I have called an axonometer, a cut of which is here shown. It is a gutta-

percha disc, one and one-half millimeters in thickness, of the diameter of the ordinary trial-lens and mounted in a cell of the trial set with a milled edge. It has a central round opening twelve millimeters in diameter, the diameter of the average cornea at its base.

Two heavy white lines, one on each side, pass from the circumference horizontally across to the central opening, bisecting the disc. To use the axonometer, place it in the front opening of the trial-frame, and with the patient seated erect, and the frame accurately adjusted so that the cornea of the eye to be refracted

occupies the central opening, proceed as in the usual method of making the shadow-test.

As soon as that lens is found which corrects the meridian of lowest refraction, and the band of light appears distinct, turn the axonometer slowly until the two heavy white lines accurately coincide, or appear to make one continuous line with the band of light. The degree-mark on the trial-frame to which the heavy white lines then point is the exact axis for the cylinder.

The little device seems to possess the following points of merit:

1. Simplicity.
2. Accuracy.
3. Small expense.
4. It covers an unnecessary part of the trial-lens, which too frequently gives annoying reflexes and images.
5. It saves time, avoids the statement of the patient, and renders the ophthalmometer unnecessary.
6. Its color (black) absorbs the superfluous light-rays from the skiascope, and gives a stronger contrast to the reflex and central shadow.
7. Limiting the field of vision in children, it permits of more concentrated attention.
8. For children and nervous patients, when it is difficult to use the ophthalmometer, this simple appliance is of great service.

To add to the usefulness of this instrument (which is also made plain, as described), I have had stamped on its periphery, in white lines and figures, the degrees in reverse order to those on the trial-frame, thus making it a very serviceable cylinder protractor.

1630 Arch Street.

MEDICAL PROGRESS.

A Woman with Two Distinct Uteri.—At a recent meeting of the Philadelphia County Medical Society, Dr. Hannah T. Croasdale reported the case of a woman, aged sixty-three years, who came under observation for treatment for an abdominal tumor. Twenty years before, she had noticed some enlargement of the abdomen, which in five years had reached its existing dimensions. No discomfort had been felt (except from the size) until recently, when she had experienced pain and pressure-symptoms, and the bladder and rectum had become very irritable. The menopause occurred at fifty, and at that time the woman was confined to bed for several weeks, but no especial reason for this could be learned. Her condition on admission was not very good, although no definite trouble could be found except a systolic heart-murmur. Lungs and kidneys were in good condition. Pelvic examination externally showed a regular enlargement of the abdomen, and there was percussion-dulness from the symphysis pubis to the umbilicus and almost from crest to crest of the ilia, with a small area of tympany on the left side.

On making digital examination *per vaginam* the cervix uteri seemed small, apparently having undergone senile atrophy, and it was pushed backward and high in the pelvis, the whole uterus also being pushed backward. It was thought that the fundus looked forward, but the uterine sound did not pass readily, hence its use was not persisted in. What seemed to be a fluctuating tumor was appreciated *per vaginam* to the right of the uterus and above the brim of the pelvis, and a small, tender mass was felt in the right parametrium. The patient complained of pain and tenderness when touched, especially on the right side. A diagnosis of fibro-cystic tumor of, probably, the uterus was made, and, after the usual preparation, the patient was etherized and the abdominal cavity opened. The omentum was found to be greatly thickened and congested, and extensively attached to the tumor beneath it and to the pelvic walls. It was necessary to ligate and cut in many places, and upon pushing the omentum aside the tumor looked pale and felt and looked like a fluctuating mass. A trocar and canula was used, but no fluid flowed through the canula.

The incision was now extended in the abdominal wall upward sufficiently to admit of the withdrawal of the mass entire.

A small nodular mass, attached to the lower part of the tumor, having the shape and size of the uterus and furnished with what seemed to be the uterine appendages, was drawn out of the lower end of the wound, and was found to be attached by a small cord-like pedicle to the pelvic brim, a little below the crest of the left ilium. Another body, to all appearances a uterus with its appendages, was found in the pelvic cavity and fixed by the usual attachments, but crowded into Douglas' pouch. The slender pedicle, not larger than a pencil, which tethered the smaller mass to the pelvic wall, was ligated and cut.

The tumor being now freed from its attachments, which were omental entirely, was lifted from its bed. This growth must have derived most, if not all, of its nourishment from the establishment of the circulation through the omentum, for it had almost severed its attachment from other structures, and the omental vessels were enormously enlarged.

The abdominal cavity was cleansed and the opening closed with silkworm sutures, the dressings applied, and the patient put to bed. Reaction was prompt and good. The temperature for the first four days ranged from 99° F. to 100.4° F. It then rose, and on the sixth day reached 102.6° F., and on the ninth day 105.4° F., when the woman died of septic intoxication.

The autopsy showed purulent infiltration at various points in the pelvic cavity. There was also found at the autopsy a uterus and appendages in a healthy condition and in the proper position.

Sections from the little body which hung from the large tumor were sent to two pathologists. One reported the specimen as being that of the structure of a fibro-myoma. The other pronounced it uterine tissue, and some structure resembling the endometrium.

This second uterus had developed from its *cervix* a fibro-myoma. As it grew too large for the pelvic cavity and rose above the brim, the little organ was inverted and so hung suspended from it.

It measured one and one-quarter inches from the internal os to the fundus. The length and size of the cervical portion were exaggerated, evidently from the tension upon it, but as it was cut open in the fresh state it showed quite distinctly the arbor vitæ arrangement o the mucous membrane lining the canal, and the lips and cervical canal were quite natural in appearance. The

os internum on the left side admitted the passage of a small probe, which passed a little distance along the Fallopian tube. On the opposite side the opening would not admit of the passage of the probe. There were two small ovaries which, on being cut open, showed on macroscopic inspection ovarian tissue. No microscopic examination of this tissue had been made. In the cervical canal, just below the internal os, was a small calcareous deposit.

Successful Dilatation of a Constricted Pylorus.—O'Hara (*Australian Medical Journal*, vol. xv, No. 12, p. 615) has reported the case of a woman, thirty-nine years old, who for two years had suffered with impaired digestion and failure of appetite, and who for six or eight months had been growing progressively worse. There was frequent nausea, attended with vomiting, especially in the morning. Food was frequently rejected shortly after being taken. The ingestion of food was attended with a sense of weight and oppression in the epigastrium, flushing of the face, a bad taste, and dryness of the mouth, with palpitation of the heart. For a year there had been slight redness on the left side of the root of the nose, which had spread to the alæ, and later appeared on the forehead and the cheeks. This condition had been growing worse for three months, and was attended with tension of the skin, bright hyperemia, and burning pain. Forty-two pounds in weight had been lost in five months. On physical examination the stomach appeared dilated and the pylorus thickened. For a time lavage and tonic treatment were employed, but the symptoms persisting, an exploratory examination of the pylorus was determined upon. The contents of the stomach were evacuated by siphonage, and boric acid introduced into the cavity. After the abdominal cavity had been opened, an incision was made with a blunt scissors into the anterior wall of the stomach near the pylorus. The gastric contents were caught upon sponges. The pyloric orifice was found to be constricted, and by means of an ivory glove-stretcher was sufficiently dilated to admit a finger. The dilatation was continued until another finger could be introduced. The wound was then closed and the patient returned to bed. Recovery was uninterrupted, and in the course of the following six weeks the woman had gained twelve pounds in weight. Three years later her health was still good.

Diphtheria of the External Auditory Canal.—Treitel (*Deutsche medicinische Wochenschrift*, 1893, No. 52, p. 1388) has reported a case of pharyngeal diphtheria, in a child three years old, in which, notwithstanding the absence of involvement of the middle ear, membrane formed in both external auditory canals, upon the left side involving also the auricle. Bacteriologic examination of a portion removed disclosed the presence of bacteria that resembled diphtheria-bacilli, but cultures were unsuccessful. The child died from cardiac asthenia.

THERAPEUTIC NOTES.

Poisoning by Chloralose.—Williams (*Practitioner*, No. 308, p. 98) has reported the case of a highly neurotic woman, forty-two years of age, in whom toxic symptoms appeared after taking ten grains of chloralose on each of two successive nights. The patient had for a number of years suffered from "spinal neuralgia," among other symptoms of "neurasthenia," although not hysterical. Her pulse was always feeble and small, though regular, but there was no indication of cardiac disease. Complaining of neuralgic pain in the lumbar region, extending round the abdomen and preventing sleep, the woman was one night given ten grains of chloralose suspended in milk, with which she had a fairly good night. She complained of the bad dreams that the drug had induced, but there were no disagreeable after-effects on the following morning. At night the woman took another dose of ten grains of chloralose. Half an hour later she became very excited and restless, and soon began calling out. This condition of acute delirious mania continued for several hours, the woman appearing conscious of the presence of others, but apparently not recognizing anyone. Her pulse was unusually good; the pupils were unaffected; restraint was forcibly resisted, especially on attempts to give a hypodermatic injection, such as she had frequently received on other occasions and the nature of which she appeared to recognize. An injection of quarter of a grain of morphin, followed in half an hour by another of a sixth of a grain, did not produce any quieting effect at all. Recovery, however, took place in the course of a few hours more, although the woman was wholly unconscious of what had taken place. On the following morning she was prostrate, but without headache, and without recollection of anything that had happened after the taking of the dose of chloralose.

Poisoning by Diachylon Ointment.—Passler (*Münchener medicinische Wochenschrift*, 1894, No. 5, p. 84) has reported the case of a child, a year and a quarter old, that had an attack of erysipelas of the head at the age of four weeks, from which it made a good recovery, without complication. Shortly thereafter a generalized eczema developed, which resisted ordinary therapeutic measures. For this condition a gauze bandage, upon which a thin layer of diachylon ointment was spread, was applied to the lower extremities. The eczema soon assumed an improved appearance, but the child became unusually quiet and apathetic, while marked edema developed in the lower extremities, and but a few drops of dark, cloudy urine were passed in the twenty-four hours. The bandages were at once removed, and the ointment detached by means of a warm bath. Examination of the urine disclosed the presence of albumin, blood, colorless and red corpuscles, hyaline and granular casts, with epithelial cells and blood-cells. The mucous membrane of the mouth was red and swollen, and there was an excessive secretion of saliva. The child gradually improved and the symptoms successively subsided, although dilatation of the left ventricle made its appearance. All of the abnormal manifestations, however, finally disappeared. The presence of lead could not be detected in the urine, and there was no blue line on the gums. Partly by a process of exclusion, and partly by a correlation of attendant circumstances, the conclusion was reached that the whole train of symptoms owed their origin to the absorption of the lead contained in the ointment employed in the treatment of the eczema.

THE COMING SANATORIUM.

AN artificial sanatorium, ideal in character and strictly unobjectionable as a refuge for invalids, does not exist. In fact, until the more recent evolutions and revelations in biologic, physiologic, and therapeutic knowledge had made known the decided and growing necessity for it, such an institution was an impossibility, because yet uncalled for and unconceived. But the search-light of alert and reinforced modern science has now thoroughly warned us of the inadequacy of the older methods of constructing and administering health-institutions. The demand for a new system and new conditions to meet the new requirements and to obviate the systems now in vogue, is being widely recognized and is daily becoming more pronounced. As evidence of this fact, leading medical journals and sanitary publications are all directly or indirectly agitating the subject; and already in several States, legislation looking toward a better appreciation of dangers that constantly menace the community through non-observance of sanitary precautions formerly overlooked, but now known to be of vital importance, is being enacted. Witness the action of the American Health Association, the Pan-American Medical Congress, the French League for the Prevention of Tuberculosis, the Philadelphia Society for the Prevention of Tuberculosis, etc., as referred to in a recent issue of THE NEWS.

The revolution, or more properly the stage of evolution, is therefore upon us, whether we fully realize it or not.

To elevate the art of medicine to a standard quite equal to that already attained by her sister arts, and to advance her well on toward the dignity of a science, to which proud appellation she as yet has no strongly-valid claim, at least two fundamental objects must be kept to the fore:

1. To make more generally available, in the treatment of human diseases, defects, and deformities, all such rational methods, influences, agencies, processes, materials, and methods of procedure as have thus far proved efficacious in preventing the onset of disease, in removing all removable conditions on which physical impairment depends, and in overcoming impediments to normal functional activity, thereby "curing" or greatly ameliorating many forms of disease that, heretofore considered incurable, are now known to be amenable to a judicious application of methods, influences, and resources which until recently were either unknown or unappreciated.

2. The inculcation and wider dissemination of *sanatory*, as well as *sanitary* science, in accordance with the most advanced light at present available on these vitally important subjects, through modern biologic, physiologic, and chemic researches and demonstrations.

To inaugurate this movement in an efficient, thorough, and practical manner will require a restatement and revival of the now almost obsolete Art of Living, and the adoption of a new system of sanatory education, fundamental in character, based on natural laws and the revelations of modern science, and calculated to develop, complement, and harmonize this complex embodiment we call human nature, considered in all its aspects—physical, mental, social, psychic, and moral.

True, this work promises most for the generations to come, but it must have its inception with those who are now on the stage and championing the cause of vital science. For present-day benefits we must look to a new departure in the utilization of prophylactic and remedial agencies, which requires a radical innovation in the methods of founding, equipping, and administering sanatoria and every kind of resort for invalids.

If there be one hygienic law better established

than another it is that zymosis, contagion, and infection are the direct means of originating and disseminating many, if not all, of the widely prevailing and frightfully fatal chronic diseases, a majority of which have not hitherto been classed as either infectious or contagious. Hence, any system of treatment that does not fully and practically recognize this law must necessarily fall short of the high degree of success now known to be possible through a careful observance of the simple but imperative laws of asepsis, antisepsis, and isolation.

There can be no question but that a large number of cases, especially of tuberculous disease, which have been greatly benefited or virtually cured by a prompt resort to a propitious climate and judicious treatment, have subsequently suffered fatal relapse through being exposed to reinfection by the dried and pulverized uncared-for discharges from other cases.

Hence, if we make any pretensions to scientific consistency, we must unhesitatingly condemn and discard the prevailing practice of congregating invalids of any class whatever in crowded and no matter how "palatial" hotel-hospitals, whether they be well or illy located as to climate, natural auxiliaries, or scenic beauty. Instead of single, immense, and imposing structures, with "capacity for a thousand guests" (and countless ghosts, recruited annually from the ranks of former guests), in which large numbers of the miscellaneously afflicted are intermittently massed and brought into more or less constant and intimate contact, our invalids must be provided with *detached dwellings*, dissociated cottages, and private villas, according to their tastes and means, all to be constructed, adapted, and furnished with strict regard to the laws of asepsis and the needs and comfort of patients. This is a consummation imperatively demanded by the present attitude of sanitary science, and by accepted results of all the more recent studies and demonstrations in biology, physiology, and pathology. In no other way can the stringent and indispensable rules of prophylaxis, anti-contagion, and anti-infection be even approximately observed or enforced. In no other way can a health-seeking community or series of communities be so organized that immunity from contagion and infection—disease-transference—can be made a primary, paramount, and practical consideration.

Having solved the question of environment and habitation, it then devolves upon us to accord a more adequate and comprehensive recognition to the yet imperfectly explored realm of the *remedii naturæ*. Every effort of Nature is aimed in one of three directions—building, repair, or reproduction. As physicians it is our principal office not to antagonize, but to direct and regulate these efforts. A judicious invocation of the almost limitless resources of Nature has therefore come to be held in such high esteem by advanced minds in the profession that it must hereafter be made a pronounced and prominent feature of every curative effort. Its range is virtually exhaustless and illimitable, yet a rational comprehension of its possibilities is being steadily developed. Its trio of controlling divinities, the three prime functions of all animal life, are *aëration*, *nutrition* and *excretion*.

Aëration, as the results of half a century of physico-chemic experimentation have taught us, involves much more than the indifferently performed and greatly underrated act of respiration, important as is that commonplace function to the instant life and vital continunace of every animal organism. It is intimately involved in the relations of climate, local environment, habitation, exercise, clothing, and a thousand other modifying items and influences not usually coupled with it.

Nutrition includes everything in any way related to the vital commissariat—the building of the body, dietetics, the selection, composition, and preparation of food, and the accurate adaptation of food-elements to the wants of the organism, in health and in disease. The combined results of laboratory and clinical research and experimentation are fast making it possible to so direct and regulate the digestive and assimilative functions as to radically influence and control the activities of the entire organism, to the end that what has manifested itself as diseased action can be gradually changed into normal or healthy action; and as a consequence, the malady, whatever it may have been called, is overcome in the most thorough, rational, and lasting manner, without the delusive aid of palliatives, which merely obtund sensibilities and mask symptoms the cause of which they do not remove.

So, too, *excretion* embraces all the processes by which the system frees itself from waste products which, if retained, become virulent poisons and finally destroy the organism itself. If the emunctories are sluggish or overloaded, the deadly ptomaïns and other products of organic decay accumulate. As long as elimination keeps pace with

organic disintegration health is possible. When the equilibrium normally existing between these two processes is disturbed, disease is the result, and it becomes only a matter of time when organic dissolution will supervene. Hence, a majority of remedial measures that may be properly called curative are directed toward the acceleration of excretory processes, due regard being had for an adequate supply of proper material for replenishment and renewal.

Nor is it extravagant to assert that these three functions, considered in all their remotest bearings and relations, comprehend all that can be attempted toward the relief of those who are physically afflicted.

But it is not enough to heal the sick. Regained health is an inestimable boon for which suffering mortals stand ready to sacrifice everything at their command; but it loses half its value if its possessor does not learn how to retain it after it has been recovered. For this reason no health-institution is either complete or consistent that does not make adequate provision for the dissemination of sound and practical sanatory knowledge. It may be charged that the inculcation of such knowledge will trespass on the domain of the routine practitioner; but the present happiness and future advancement of the race are objects of paramount importance to the personal and pecuniary interests of any one class, interest, or profession. Besides, it is already conceded that the physician of the future will be a conservator of health, not a curer of disease, his art having far more to do with prophylaxis than with treatment. *The day cannot now be far distant when the existence of preventable disease will be considered a public or private crime, and when medical men will be required to study and remove causes, instead of tinkering and philosophizing over their inevitable effects.*

In comparison with the number born, how few live on to even the reasonably ripe age of threescore and ten. Judging by analogy from the known laws of biology and physiology, there is no valid reason why the average human being should not live in comfort and physical enjoyment, retaining all his faculties and functions, to the rounded term of a century; whereas, but a minority can recall a dozen strictly healthy weeks since the trying days of chicken-pox and measles. Many of us are practically toothless at twenty, bare-pated at thirty, and superannuated at fifty.

REFORMS IN COLLEGE ATHLETICS.

In The News of November 18, 1893, we ventured to call attention to the excesses permitted in the name of foot-ball by our colleges, and the consequent injury to true athleticism, to genuine educational interests, and to general social morality thereby. At the time of the appearance of our protest there was not only no considerable opposition to the game, but all important newspapers and college authorities were enthusiastically encouraging the fatal tendency. College professors and presidents were hurrahing themselves hoarse and contributing their house-doors and wood-piles for bonfires to celebrate foot-ball victories.

Following upon our word of warning the editor of The News had a *mauvais quart d'heure.* Friends warned of the danger of taking the unpopular side, and of the wisdom of obedience to the Zeitgeist. One college president wrote a personal letter that we had certainly exaggerated, and that our conclusion was not that of those who had dispassionately studied the game. A few newspapers coarsely abused, and all opponents agreed that we did not know anything of the game. We unflinchingly persisted in our contention, clinching the argument with indubitable facts—and very soon another public sentiment began to manifest itself. One powerful newspaper after another began to speak out boldly against the excesses of foot-ball and of intercollegiate contests, one great journal most flatly and completely changing its entire attitude in twenty-four hours. Despite the casuistic defences and lectures in great magazines and in Christian pulpits by learned professors and eminent divines, it was soon found that there was more sanity in the people than in at least *some* of the educational leaders. The Zeitgeist had changed its mind! Almost without exception the newspapers of the whole country were soon found upon the right side. Then began to appear articles by a number of college presidents, showing (at last!) a healthy courage and a conservative common sense. There followed the strong, manly protest of the University of Virginia, of other colleges, and college-associations. Now, like a thunderbolt, comes President Eliot's authoritative pronunciamento, in which every point contended for by The News is abundantly supported by one whose qualifications and interests are altogether beyond dispute. The University of Pennsylvania has promulgated a set of rules looking to reform of a determined character,

but still not sufficiently thoroughgoing. The Secretary of War and the Secretary of the Navy have forbidden future foot-ball contests between the cadets at West Point and Annapolis, "because such matches are detrimental to discipline and to the studies of the cadets." The victory may, therefore, be considered complete.

The victory, at least, so far as logic and expert authoritative opinion is concerned. But it must not be forgotten that the athletic associations and players are proceeding to their forced tasks, of remodelling the rules and subordinating college athletics to college duties, very much as a whipped schoolboy returns to his lessons. By open "interviews," by corporate action, or rather corporate silence, and by ill-concealed disgust, it is painfully apparent that the task is to them most nauseating. We beg them to take the matter seriously. There is no possible answer except assent, and loyal willing assent, to the fact that, as recently carried on, intercollegiate athletics do abuse, and do not educate, either the human body or the human mind, and that they are not for, but are against true education and social well-being. A game that in two countries, within two or three years, kills outright about a hundred players, and seriously injures a thousand or more, is not, in any sane or etymologic sense of the word, athletic. The element of danger necessary in healthy sport is not, of course, to be entirely eliminated, but when that element becomes the chief element, then it is high time to stop. The noteworthy statistics kindly supplied by Dr. Keen in another column should definitively settle the nonsensical claim that football is not excessively dangerous, and not more dangerous than other sports. The pity is that such an argument was needed—the facts being so patent to all. The men that founded and endowed our colleges, the glorious old Puritans, were not anemic namby-pambies or muscleless lack-adaisicals, and in shunting education into modern "athletic" excesses certain of their modern representatives are false to the trusts imposed upon them. The growth of college-rowdyism is demonstrably due to these excesses, instead, as claimed, of "athletics" being an outlet and safety-valve of youthful animal spirits. The reception of a prize-fighter by Harvard students, and by a tremendous audience at the N. Y. Madison Square Garden last week, when a prolonged series of boxing contests (held for charity's sake!) delighted upper-tendom, are startling facts that display their own lessons to those capable of appreciating them. The point we wish to emphasize is that the better part of the public is coming to recognize the true status of affairs, and that prudence would suggest to the disgruntled revisers of the rules a revision that does in reality revise, and that, in order to preserve what is good in athletic games, they must make a thoroughgoing reform, and altogether excise what is altogether bad.

EDITORIAL COMMENTS.

To Remove Certain Disabilities of the late Acting Assistant Surgeons, U. S. A.—A bill has been introduced into both houses of Congress having in view the commissioning by the President as acting assistant surgeons of the United States Army such private physicians as were employed as medical officers in the armies of the United States for a period of not less than three months and who were officially known as acting assistant surgeons of the United States Army, and whose services were honorably terminated; the date of employment as acting assistant surgeon to be the date of commission and muster into service, and the date of the honorable termination of service as acting assistant surgeon to be the date of discharge or muster out of service. It is not intended that any pay or allowance should be made by virtue of this act, or that the rank, pay, or emoluments of commissioned medical officers of the United States Army should in any way be affected. Such acting assistant surgeons as were disabled by reason of disease contracted or injury received in the military service are already entitled to pensions, under a law which assimilates them to the rank of first lieutenant of the military or marine corps. The object of the present bill is intended to remove a disability by reason of which, as non-commissioned officers, such acting assistant surgeons are denied admission to military organizations like the Loyal Legion and the Grand Army of the Republic. We see no objection against, but only good reasons in favor of the passage of this bill, which would confer official recognition upon a body of men whose services on the field entitle them to the warmest commendation and consideration. The bill has been read twice in the Senate and referred to the Committee on Military Affairs. It has also been introduced into the House of Representatives, referred to the Committee on Military Affairs, and ordered to be printed. It is requested that those who have been acting assistant surgeons, or are in sympathy with this movement, should communicate promptly with members of Congress and others who are in a position to give material assistance.

Overcrowding in the Medical Profession.—From figures given by the Berlin correspondent of the *Medical Press and Circular*, No. 2856, p. 115, it would appear that the relative and absolute number of medical men in Germany is increasing at a rate not behind that which has become a cause for concern in the United States. It can only be conceived that there must still be something exceedingly attractive about the study and the practice

of medicine that will take young men and women away from more lucrative pursuits to enter upon a life that is known to demand close application and hard work, without corresponding pecuniary remuneration. We must hope that this large increase in numbers will bring with it constant improvement in quality, professional and ethical. We fear, however, that the number of failures will be greater, but the successes will have to be won by real ability. The number of medical men in Germany at the close of the year 1892 was 20,500, whilst a year later it had increased to 21,621—a difference of 5.46 per cent. At the close of the year 1892 there were in Berlin 1636, and at the close of the year 1893, 1799 physicians—an increase of 10 per cent. During five years the increase has been 22.2 per cent. Throughout Prussia there are 12,851 medical men, an increase of 777 over the year 1892; in Bavaria there are 2431, an increase of 86; in Saxony 1563, an increase of 40; in Baden 855, an increase of 44; in Wurtemberg 739, an increase of 28; in Elsass-Lothringen 632, an increase of 33; in Hamburg 429, an increase of 8. The proportion of physicians to the population is 4.37 to 10,000, against 4.15 in 1892. In Hamburg the proportion is 6.98; in Bremen, 6.92, and in Lubeck, 6.11. Throughout Prussia the proportion is 4 28. The proportion is highest in the towns in which there are universities: In Strassburg, 17.8; in Halle, 12.1; in Munich, 11.9; in Berlin, 11.5; in Breslau, 11.3; in Königsberg, 10.6.

Subscriptions Free, the Advertisers Paying the Bills.—We have before us a medical journal that prints on its title-page, "Sent free to every member of the profession in —— ——." This has the decided merit of frankness. We have long been used to the method of exploitation in lay periodicals, consisting of giving a tremendous amount of so-called reading-matter at less than the cost of the printer's bill, but making fortunes by the advertisements secured through the large circulation. In a business sense this would seem to indicate that the price of advertisements or of subscriptions should be lowered. This "medical" journal has chosen to lower the subscription—and to zero! When such a method enters medicine as it has done—frankly in the case cited, secretly in many so-called medical journals—it is a cause for criticism. The good of the profession demands that every journal it supports, and every line of the reading-matter shall be written and published in the interests of medical science and ethics. There is only a certain amount of money that advertisers can afford to pay for advertising reputable and worthy things, because there is only a certain maximum sale for and profit in such things. It is the disreputable and worthless product that pays the big advertising bills. How can a reputable journal, published with true professional ideals, compete with journals published by the advertisers and solely in their interests? How can reputable physicians edit such journals? How can they write for them? How can they allow them to be delivered to their address?

A Singular Oversight.—In a paper occupying six entire pages of the *Journal of the American Medical Association* for February 10, 1894, Dr. J. E. Woodbridge refers to a large number of cases of typhoid fever, in which he brought about almost miraculous cures by a "special" mode of treatment, which is merely hinted at. The only explanation that can be found for withholding the important information that might have made the paper a life-saving one is contained in the expressed fear of giving "to the world a treatment that on more thorough trial might prove to be a failure in the hands of more able but less enthusiastic practitioners, and the action of which I could not then and cannot now explain." Having thus plucked up courage to detail the results of this "special treatment," we earnestly hope that Dr. Woodbridge will hasten to give to the world the details of the method that in his hands has proved so incomparably successful. As the matter stands, we are at a loss to see how the editor of the *Journal* could give up so much valuable space to a paper that tells so little of value. Is a new secret nostrum to be fathered by and foisted upon the profession? If not, why not divulge its nature and method at once? The whole affair looks decidedly quackish.

The Pharmacy Act Declared Unconstitutional.—It is reported that a physician in the western part of Pennsylvania has been acquitted of a charge of violating the pharmacy law by compounding medicines without being a registered pharmacist. The prosecutor was the President of the State Pharmaceutical Board. The judge who delivered the opinion in the case is quoted as saying that the bill was framed in the interest of druggists and that it was unconstitutional.

REVIEWS.

A Treatise on Hygiene and Public Health. Edited by Thomas Stevenson, M.D., F.R.C.P. Lond., Lecturer on Chemistry and on Medical Jurisprudence at Guy's Hospital; Official Analyst to the Home Office; and Shirley F. Murphy, President of the Incorporated Society of Medical Officers of Health; Medical Officer of Health of the Administrative County of London. In three volumes. Volume II. 8vo, pp. 847. Philadelphia: P. Blakiston, Son & Co., 1893.

The second volume of this *Treatise on Hygiene and Public Health* contains a group of valuable and interesting monographs. It opens with an extensive article upon the "Pathology and Etiology of Infectious Diseases," by E. Klein, M.D., F.R.S. The subject is treated under the following sections: Section A includes general considerations of bacteria—morphologic, biologic, and technical; Section B, the specific or pathogenic bacteria, and Section C the specific diseases. The article closes with a very large group of illustrations made from photographs and colored sketches. They are, in the main, not especially good, and convey but little idea of that for which they were designed. This is particularly true of the colored plates giving the macroscopic appearances of growing cultures. The text is a fair presentation of the subject, though conspicuously biased in many points by the individual views of the author, which have not met with general acceptation outside of England. Considerable space is devoted to the so-called milk epidemics of scarlatina, and

among others the statement appears: "These milk epidemics are nowadays so easily recognized . . . that there is hardly a health-officer in this country (England[1]) who has not had the opportunity . . . to himself investigate or become acquainted with such an epidemic." It appears to us singular that these outbreaks of scarlet fever due to milk should appear so frequently in England and escape observation in other countries. The chapter on the pathology and etiology of diphtheria is remarkable for the entire absence of any mention of the peculiar cell-necrosis described by Oertel in the tissues of the human subject dead of this disease, and by Welch and Flexner in animals that have succumbed to the experimental form of diphtheria. The comments upon the cultural peculiarities of the bacillus diphtheriæ of Loeffler leave but little room for doubt that part, at least, of Klein's work on this subject has been done with organisms other than the genuine bacillus diphtheriæ, and which have been mistaken for it. There are many details to which the specialist might take exception, but these do not diminish the value of the article for the general reader.

The monograph upon "The Natural History of Infectious Diseases," by T. W. Thompson, opens with some generalizations upon the history and causes of diseases. As each disease is considered it is treated under the following heads: Synonyms (Eng., Fr., Ger.); history and geographic distribution; periodicity; influence of climate and of seasons; mortality; fatality; influence of race, sex, age; modes of dissemination; period of incubation; and protection. It will be seen from these headings that the article contains much valuable and instructive matter.

"Smallpox and Vaccination," by John C. McVail, M.D., F.R.S.E., contains a history of the disease; its distribution; periodicity; fatality; cause and mode of dissemination; protection. Among other things, the article contains numerous charts that represent graphically the relative frequency of the disease in various localities, and in large groups of vaccinated and unvaccinated individuals.

The balance of the volume is given to articles on vital statistics; marine hygiene; military hygiene; disposal of the dead; and the medical officer of health. As a whole the volume is creditable alike to authors, editors, and publishers.

A Text-book of Physiology. By M. Foster, M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, and Fellow of Trinity College, Cambridge. With illustrations. Sixth edition. Part I, comprising Book I: Blood. The Tissues of Movement. The Vascular Mechanism. New York and London: MacMillan & Co., 1893.

No more conclusive proof can be offered of the continued interest and activity in the investigation of physiologic processes than the appearance of numerous manuals, compends, and text-books, and the necessity for new and revised editions of those that have already found favor with students and physicians. It is a recognition of the truth that not only histology, but also physiology, or a complete knowledge of the physico-chemic processes that underlie all normal vital phenomena, constitutes the essential basis for a correct interpretation of pathologic and clinical phenomena.

Among the many books that have been published within the last ten years none has met all the requirements so satisfactorily and attained so wide an acceptance as the text-book of Prof. Michael Foster. Originally published as a single volume of small dimensions, it has grown with the advance of physiologic knowledge, until it now presents itself in five complete parts, aggregating nearly two thousand pages. It is not difficult to account for the popularity of this work in both England and America. The clearness of conception and the judicial presentation of physiologic problems are unsurpassed, and make the work a readable and instructive one for both advanced students and practitioners. Without overburdening the text with descriptions of apparatus or unnecessary anatomic details, the central idea of each subject is elucidated and illustrated by appropriate histologic facts and brief statements of the principles involved in any given physiologic method.

Of this sixth edition several parts have already been published. The original appendix on "The Chemical Basis of the Animal Body," written by A. Sheridan Lea, appeared in an enlarged and revised form as a separate but complementary part about a year ago. Part IV, comprising an account of the physiology of the special senses, was also published last winter. This section of the work was very much enlarged over that of the previous editions. Part I, which has just been issued, comprises the blood, the tissues of movement, and the vascular apparatus, and is practically a reprint of the fifth edition, with the exception of some thirty pages of additional matter pertaining to the cardiac beat. The author here revises the former account of the beat, and incorporates, with customary clearness, the results of the investigations of Hürthle, Frey and Krehl, and others, as to the characters of the endocardial pressure and its relation to the aortic pressure, and the bearing which both have on the pulse-wave and its interpretations.

The succeeding part of this valuable work will no doubt bear the impress of the author's wide and accurate knowledge of the subject.

Essentials of Minor Surgery, Bandaging, and Venereal Diseases. By Edward Martin, A.M., M.D. Second edition, revised and enlarged. 78 illustrations. (Saunders' Question-Compends, No. 12.) Philadelphia: W. B. Saunders, 1893.

In preparing the second edition of this little book the author has revised it thoroughly so as to bring it, as he says in his preface, "up to the present standard of surgical practice." The section on the roller bandage is improved by the excellent illustrations and descriptions borrowed from the *American Text-book of Surgery*. These cuts are admirably executed and clearly portray the various bandages they serve to illustrate, and will doubtless be appreciated by students, for whose use the book is intended.

In the 166 pages which comprise this volume the author has succeeded in getting over his ground, in question and answer style, as well as could be expected. The answers to the questions, while clearly expressed, and therefore easily fixed in the student's memory,

[1] Parenthesis ours.

sometimes tend to be superficial, a fault which, however, in a book like this it is not easy to avoid.

Transactions of the State Medical Society of Wisconsin for the Year 1893. Vol. XXVII. Madison, Wis.: Tracy, Gibbs & Co., 1893.

The quality of the papers contained in this volume is for the most part good, and gives evidence of the high standard of the scientific proceedings of the meetings at which they were read. Contributions of notable excellence are: that by Levings on the "Present Status of Surgery," in which he admirably exposes the advances of modern surgery; a paper by Reineking on the "Surgery of the Trifacial Nerve"; "Intestinal Anastomosis," by Ladd; "Pleural Effusions: their Diagnosis and Treatment," by Batchelor; "Renal Neoplasms, with Report of Two Cases of Nephrectomy," by Mackie; Copeland's paper on "Drainage after Operations on the Pelvic Organs"; Hamilton's on "Tumors of the Bladder"; and Würdemann's on "The Treatment of Chronic Suppuration of the Middle Ear by Removal of Carious Ossicles, Necrosed Bone, and other Obstructions in the Tympanum."

The book has a neat appearance, and the typography is excellent.

CORRESPONDENCE.

LETTER FROM LONDON.

[From Our Special Correspondent.]

Who Shall Treat Diseases of the Digestive Tract?—The Treatment of Influenza, of Diphtheria, and of Rectal Disease—Scurvy in Children—Brunton on Headaches—The Allyl or Garlic Treatment of Tuberculosis.

"Surgery," it has been said, "is superficial medicine." To which, by way of retort, it has been added that medicine is surgery in the dark. Mr. C. H. Watts Parkinson, an eminent local practitioner in the Southwest of England, and President of the Bournemouth Medical Society, in one of those homely and unscientific addresses which often contain many grains of cultivated experience and sound common sense, observed that the treatment of inflammation of the bowels—or typhlitis, perityphlitis, and appendicitis—seemed now to be passing from the physician to the surgeon. In these days of antiseptic surgery it is dangerous to take a case of gastric disease to a surgeon for fear he will want to explore the interior, and it seems that every case of inflammation in the right flank is due, or ought to be due, to that wretched mistake of Nature—the appendix ceci. But, after all, are these cases so dangerous, as a rule, that they need an operation? How common they are, and how few are serious! The only fatal case he had seen was in consultation, in which the medical man had been treating with a course of white mixture. And here he recommended the method of examining the liver and abdomen suggested recently by Mr. Arbuthnot Lane, of Guy's, in the *British Medical Journal*, viz., making the patient sit astride on a chair, with the body well bent forward and the arms hanging over the chair, the surgeon standing behind and passing his arms round the body.

Of course, he had something to say about the treatment of influenza. His contribution was as follows: "As a general routine treatment, I believe in salicylate of soda, to which I always add a little nux vomica, milk-diet, with a little whiskey and milk when the crisis has set in and perspiration is profuse, and plenty of blankets. I have had to make the *experimentum in corpore vili* three or four times, and whereas before I took the salicylates I was laid up a week or more, the last two attacks, apparently equally severe (temperature from 102° to 103°), only kept me from work forty-eight hours. I think the addition of the nux vomica most useful in counteracting the depressing influence of the disease and the salicylates."

For diphtheria he recommends the trial of an old remedy, viz., chlorin in solution. "I have used it now some years for diphtheria and sore-throats, and have not had a death. Last year a woman and four children were attacked in one house; two children first attacked were dead before medicine could reach them; the others did very well, and recovered without any sequelæ." He uses potass. chlor. gr. 40, acid. hydrochlor. fort. ℥ 40. Put the powder in a dry bottle, add the acid, cork, and shake well; when chlorin is evolved, add water gradually to eight ounces, shake, and add glycerin. In scarlet fever he recommends the treatment by perchlorid of mercury and biniodid (as recommended by Dr. Illingworth), added to inunctions of eucalyptus oil (recommended by Dr. Curgenven), or some other antiseptic; this treatment is, in his opinion, the best and most likely to modify the disease and also the period of infectivity.

Dr. Clifford Allbutt, although Regius Professor of Medicine in Cambridge University, has not forgotten his Leeds experiences, according to which a large number of cases of irritation of the rectum, associated or not with hemorrhoids or fissure of the anus, are cured often at once by dilatation of the sphincter ani. What he advocates is not a mere passing of large bougies, but the introduction of the two thumbs of the surgeon into the orifice, under an anesthetic, of course, and the forcible separation of them until the muscle is felt to creak and give way under the strain. The degree of stretching so produced is no small one, and in the case of a toughened adult sphincter, may require something like the full strength of the operator. If any incontinence follow, it never lasts more than a day or two. The *rationale* of the condition which this operation so markedly relieves is probably that, as a result of irritation, a spasm of the muscle is set up, which may persist after its cause has passed away, and may even lead to hypertrophy and degeneration of the muscle into a hard, comparatively-rigid fibrous ring. Dr. Allbutt also states that many cases of obstinate constipation, especially among women, are relieved by forcible bimanual dilatation of the sphincter ani.

Dr. Sutherland draws attention to the occurrence of scurvy among children. It is a food-disorder, being always associated with a deficient supply of sound fresh animal or vegetable products, and in many cases with the employment of a diet quite unsuited to an infant's digestive powers, and he says there is no doubt that the increase of scurvy among children during the last fifteen years is largely due to the recent extensive substitution of proprietary infants' foods for cows' milk or breast-milk and natural vegetable products. Probably

it would be still more common but for the fact that children so often get potatoes and fruit and that the antidote is thus supplied. The great mass of cases occur between the seventh and the twenty-fourth month. In most cases the disorder is associated with rickets, with the common signs of which its own symptoms are a good deal intermingled. There is an exaggeration of the listlessness and dislike to being moved, which is so common in that disease, but when subperiosteal effusion takes place there is intense pain in one or more limbs with complete loss of power in them. The thigh is the most commonly affected in this way, and the skin becomes tense and glistening, but not inflamed. The gums round such teeth as have been cut are swollen and tend to bleed, but are often merely pale in other parts. There is edema of one or both eyelids, or about the ankles, and there are often subcutaneous hemorrhages. The treatment is fresh milk, fresh fruit, and fresh vegetables. In small infants the juice of fruit, such as oranges, grapes, etc., may be squeezed into the milk. Sunlight and fresh air are useful, but the child must be kept in bed till the breathlessness due to the anemia is past.

Dr. Lauder Brunton, speaking of nervous, or so-called bilious headaches, draws attention to the importance of such a remedy as is required being taken early before the headache has completely taken possession; when a headache has once fully developed, absorption by the stomach is so completely checked that nothing but the hypodermatic injection of morphin does much good. This probably is the cause of the variability observable in the action of such remedies as antipyrin. In many cases, however, headaches give a warning of their coming, and then a dose of thirty grains of potassium bromid with from five to fifteen grains of sodium salicylate will often prevent their further progress. This warning is often a little irritability in the evening; in this case the dose should be taken then; and if, on awaking in the early morning, there should be the feeling of weight in the head which is the precursor of the undeveloped attack, the dose should be repeated or taken for the first time if that is the first indication; and a third dose may be taken in the morning. The great thing is to trust to the warning and get in the medicine before the attack develops. Dr. Brunton, however, emphasizes very strongly the great frequency of the causal relation of ocular defects of accommodation with nervous headache, between 80 and 90 per cent. being due to visual defects, about 10 per cent. to decayed teeth, and about 5 per cent. to disorders of the nose, throat, and other causes.

The continually advancing experience of the value of hygienic treatment of tuberculosis does not hinder men from seeking for some medicinal means of checking the development of the tubercle-bacillus within the body. For the last suggestion we are indebted to Dr. Vivian Poore, who has come to the conclusion that garlic not only ought to be, but is, curative in pulmonary tuberculosis. Inhalations of many substances have been tried, but it is very doubtful how far they are beneficial, except in alleviating cough; for not only is the vapor which can be inhaled very dilute, but the bacilli to be attacked lie within the tissues rather than on the surface. If an antiseptic is to do good it should be something which is absorbed by the stomach, mingles with the blood-stream, and is eliminated by the lungs. The allyl compounds, such as allylic alcohol and oil of mustard, have been shown by Koch to be strongly antiseptic. It is well known that onions and garlic contain the active principle "allyl," which is largely excreted by the breath; and it seems not unreasonable to believe that a body such as garlic, which even in small quantities persistently taints the breath, might have some utility in pulmonary tuberculosis. Dr. Poore has found garlic of distinct service in cases of dilated bronchi with fetid expectoration, and although some people might say that esthetically there was but a change of smells, the point is that the fetor of decomposition disappears, showing that a distinct effect had been produced. But cases of undoubted tuberculosis have also been treated with garlic, with markedly beneficial results, one case of laryngeal tuberculosis in which the characteristic swelling was very obvious, showing a complete retrogression of the physical signs. Usually the garlic was given in the food, a "clove of garlic" being chopped up and boiled with the beef-tea, but it also can be administered as an extract enclosed in gelatin capsules.

FOOT-BALL AT WEST POINT.

To the Editor of THE MEDICAL NEWS,

SIR: At your request, I very gladly give you the facts which I stated on Tuesday night during the debate on foot-ball at the Contemporary Club. So far as I know, this is the first contribution giving an accurate comparative statement of the injuries from foot-ball, riding, and in the gymnasium, among the same class of men, with an analysis giving the percentages.

It is very evident that the actual number of accidents from riding, shooting, drowning, etc., is no guide as to the relative danger of these sports, unless we also know the actual number of persons engaged in each, and from these facts can deduce the percentages of danger.

With the kind consent of Surgeon-General Sternberg, of the U. S. Army, I addressed a letter to Major P. F. Harvey, the Post-Surgeon at West Point, and received from him the subjoined table, giving the list of casualties and the number of men, the number of accidents, and the number of days lost. I should add that the percentages under each of the tables are additions of my own:

LIST OF CASUALTIES AMONG U. S. CADETS FROM SEPT. 1, 1893, TO NOV. 30, 1893, DUE TO FOOT-BALL AND INSTRUCTION IN RIDING AND GYMNASTICS.

Foot-ball.				Riding.	Gymnasium.	
Sprains.		Contusions and lacerations.	Fracture both bones of leg.	Injuries of all kinds.	Injuries of all kinds.	Remarks
Severe.	Slight.					
4	32	17	1	17	9	Injuries in riding and gymnasium usually very slight.

I. *Number of Men.*

Number of Foot-ball players (approximate)	34
" under instruction in Riding Hall	184
" " " " Gymnasium	106

II. *Number of Accidents.*

Foot-ball	54
Riding	17
Gymnasium	9
Total	80

Percentage: 54/34 = 1.6 per man in foot-ball.
17/184 = 0.09 " " in riding.
9/106 = 0.08 " " in gymnasium.

III. *Days Lost.*

From foot-ball accidents	277
" injuries in riding	57[1]
" " " gymnasium	11

A. Percentage of days lost per man engaged in playing:
277/34 = 8.01 days in foot-ball.
57/184 = 0.31 " in riding.
11/106 = 0.15 " in gymnasium.

B. Percentage of men off duty per diem:
277/90 = 3.01 men in foot-ball.
57/90 = 0.63 " in riding.
11/90 = 0.12 " in gymnasium.

C. Percentage of days lost per accident:
277/54 = 5.01 days in foot-ball.
57/17 = 3.04 " in riding.
11/9 = 1.02 " in gymnasium.

1. *Percentage of accidents.* From the table the following deductions may be made: First, the *percentage of accidents per man* playing in the place, and for the season to which this table refers, was *twenty times as frequent in foot-ball* as in riding or in gymnastics (1.6 : : 0.09 : : 0.08, II).

2. The *number of days lost from foot-ball accidents per man playing is twenty-six times as much in foot-ball* as compared with riding, and *over fifty times* as much as from gymnastics (8.01 : : 0.31 : : 0.15, III A).

3. The *number of days lost per man injured* is 5.01, 3.04, and 1.02 (III C), showing that the foot-ball accidents in the table were nearly *twice* as serious as those from riding, and *five times* as serious as those from gymnastics.

4. *Number of men continuously off duty.* There were *five times* as many men off duty per diem from foot-ball accidents as from riding accidents, and *twenty-five times* as many as from gymnastics (3.01 : : 0.63 : : 0.12, III B). It must be remembered, also, as Dr. Harvey says in his letter, that "in addition to the cases enumerated, there were, of course, others which were either very slight or temporary, or failed to come under observation on account of pride," etc. This, however, is an observation which would probably apply equally well to any of the other accidents. It may be added also that the relative proportion between foot-ball and riding accidents is much more unfavorable to foot-ball, from the fact that twenty-seven days of the whole fifty-seven lost in riding were due to a single case, leaving therefore thirty days to be divided among the other sixteen accidents from riding. And when one considers the "dare-devil" character of the riding at West Point, it seems to me that the liability to accident would be perhaps greater there than among those who ride more quietly. On the other hand, however, we must remember that the West-Point riders are among the best trained and most competent in the country, and hence accidents would be comparatively few, perhaps less than among the general public.

It may be objected that any inferences drawn from one period of only three months might well be erroneous. I do not know whether records are kept at West Point of the casualties of several years past, but I have written to inquire. Certain it is that any disproportion within the limits of a normal law of variation cannot be said, it seems to me, to account for the fact that the accidents in foot-ball, both in number and in character, as compared with those from riding and gymnastics, were so much more frequent and serious.

My own opinion, as a surgeon who has seen a large number of accidents, is that foot-ball, *as played at present*, is a needlessly dangerous sport. The price paid for the good it does is too high, both in life and limb. Strip it of its needless dangers, and no one would be a more hearty advocate of the game than I. This revision of the rules to eliminate its dangers must be made by foot-ball men themselves. If they do this the game will hold its present place in the esteem of all who value manly and invigorating sport. If they do not, then it should be prohibited, at least in our colleges where the faculties have the power to do so. Prohibit it there, and it will be doomed to an "innocuous desuetude."

Very respectfully yours,

W. W. Keen.

1729 Chestnut Street, Philadelphia, February 15, 1894.

[1] 27 days of this, in one case, due to kick of horse on shin, causing periostitis.

AN HISTORIC CASE.[1]

A Case of Extra-uterine Fetus, described by Mr. John Bard, Surgeon at New York, in a Letter, dated 1759, to Dr. John Fothergill.

Mrs. S., the wife of a mason, about twenty-eight years of age, having had one child without any uncommon symptoms, either during her pregnancy or labor, became, as she imagined, a second time pregnant. She was more disordered in this than in her former pregnancy, frequently feverish, the swelling of her belly not so equal, nor the motion of the child so strong and lively. At the end of nine months, when she expected her delivery, she had some labor pains, but without a flow of waters or any other discharge. The pains soon went off and the swelling of her belly grew gradually less; but there still remained a large, hard, indolent, movable tumor, inclining a little to the right side. She had a return of her menses, continued regular five months, conceived again, and enjoyed better health; the swelling of her belly became more equal and uniform, and, at the end of nine months, after a short and easy labor, she was delivered of a healthy child. The tumor on the side had again the same appearance as before her last pregnancy. Five days after delivery she was seized with a violent fever, a purging, suppression of the *lochia*, pain in the tumor, and profuse fetid sweats. By careful treatment

[1] This communication was read in London on March 21, 1760, and has been kindly furnished by Dr. F. G. Devereux, of Kezar Falls, Maine. The transcription was made from an old medical volume published in London in 1762, and was suggested by the Address of Dr. McMurtry, published in The Medical News of February 17, 1894.

these threatening symptoms were in some measure removed; but there still remained a loss of appetite, slow hectic fever, night-sweats, and a diarrhea. To the tumor, which continued painful and gradually increased, were applied fomentations and emollient poultices; and at the end of nine weeks I perceived so evident a fluctuation of matter in it, that I desired Dr. Huck, physician to the army, to visit this patient with me, and be present at the opening of it. From the whole history we concluded that we should find an extra-uterine fetus. I made an opening in the most prominent part of the tumor, about the *middle* of the *right rectus muscle*, beginning as high as the navel and carrying it downward. There issued a vast quantity of extremely fetid matter, together with the third phalanx of a finger of a child. Introducing my finger into the abscess I found an opening into the cavity of the abdomen by the side of the rectus muscle, through which I felt the child's elbow. I then directed my incision obliquely downward to the right ilium, and extracted a fetus of the common size at the ordinary time of delivery. The frontal, parietal, and occipital bones, as also the third phalanges of the fingers of one hand, separated by putrefaction, remained behind; which I also took out. We imagined the placenta and funis umbilicalis were dissolved into pus, of which there was a great quantity. By the use of fomentations and detersive injections, while the discharge was copious, fetid, and offensive, and by the application of proper bandages and dressing with dry lint only, when the pus became laudable, the cavity contracted, filled up, and was cicatrized in ten weeks. The source of the hectic being removed, with the help of the bark, elix. of vitriol, and a proper diet, she quickly recovered good health. Her milk, which had left her from the time she was first seized with the fever, returned in great plenty after the abscess was healed, and she now suckles a healthy infant. I am, Sir, with great respect,

Your most humble servant,

JOHN BARD.

New York, December 25, 1759.

NEWS ITEMS.

The Medical Society of the State of Pennsylvania, at its last meeting, appointed a Committee on Scientific Business, consisting of Drs. Dulles, of Philadelphia; Gorgas, of Harrisburg; LeMoyne, of Pittsburg; Tyson, of Philadelphia; and Towler, of Marienville, "To secure scientific papers, and to provide scientific discussions for each annual meeting, and to coöperate with the Committee of Arrangements and Credentials in arranging the program." The object of this innovation is to have a permanent committee which, becoming familiar with the subject, shall find it easier to secure good scientific work than is possible for a committee that is appointed new every year.

The Committee hopes that each member of the State Society will aid it in attempting to make the meetings of the Society of greater scientific importance than they have been in the past. To this end the Committee will welcome suggestions from any member of the Society, and especially, at this time, offers of contributions to the work of the next meeting, at Gettysburg, from May 15th to 18th. It is desired that there should be as many brief, concise, practical papers as possible, and it is proposed to have a discussion on Tuberculosis, devoting the morning to "Medical Tuberculosis," and the afternoon to "Surgical Tuberculosis."

Any communication from members of the Society in regard to the work of the Committee will be welcomed.

Members of the Society desiring to read papers, or to take part in the discussion on Tuberculosis, will please notify the Chairman of the Committee, Dr. Charles W. Dulles, 4101 Walnut Street, Philadelphia.

The American Medical Association.—Arrangements are in progress providing for a special train of Pullman cars, including dining accommodations, leaving Omaha and Denver during the last week in May, by way of the Union Pacific Railroad, stopping at Salt Lake City, and reaching San Francisco in time for the meeting of the American Medical Association. The return trip may, if desired, be made by steamer via Portland and the Oregon Short Line. An endeavor will be made to have the rates of fare even lower than those specially made for the Mid-winter Fair.

The excursion will be in charge of Dr. George Wilkinson, of Omaha, Secretary of the Nebraska State Medical Society, and editor of the *Omaha Clinic*, who will be glad to receive suggestions or give additional information to those who may desire it.

Eleventh International Medical Congress.—Prof. H. J. Johnston-Lavis, 7 Chiatamone, Naples, desires to inform American attendants upon the Eleventh International Medical Congress that he will be pleased to aid and advise them during during their stay at Naples.

Il Policlinico is the title of a new Italian journal published twice a month, and under the editorial care of Dr. Guido Baccelli and Dr. Francesco Durante.

KATATONIA, WITH SIX ILLUSTRATIVE CASES.

BY E. D. BONDURANT, M D.,
ASSISTANT SUPERINTENDENT OF THE ALABAMA INSANE HOSPITAL AT TUSCALOOSA.

IF one sets out to discover from the text-books and neurologic journals whether or not there is such a disease as katatonia, and if so, in what this disease consists, he will probably emerge from the study of the already voluminous literature of the subject in a state of considerable doubt and perplexity, and with a vivid realization of the defects and inaccuracies of the several existing systems of classification of mental disorders. Quoting the definitions of two English writers, we find that katatonia is "characterized by a pathetical emotional state and verbigeration, with a condition of motor tension"; and that it is a "cerebral disease with cyclical symptoms ranging in succession from primary melancholia to mania, stupidity, and dementia, one or more of these stages being occasionally absent [how many of the four stages may be absent and still leave us a katatonia?], whilst convulsive and cataleptoid symptoms [both?] accompany the mental changes."

The published accounts of the disease differ in many particulars, and the reported cases show a wide variation in symptoms; but the more typical cases, we are told, pursue some such course as the following: Beginning as a primary melancholia, usually in a subject exhibiting evidences of the insane constitution, the emotional state soon changes to excitement or exaltation of a peculiar kind, with systematized delusions of a grandiose nature, accompanied by "verbigeration"—*i. e.*, meaningless repetition of words and phrases in a theatric or declamatory manner; or we may have a simple acute mania, or a melancholia agitata; this stage terminates after a longer or shorter time in stupor or apathy, with cataleptoid symptoms, mutism, and not rarely convulsive seizures of some kind; or, the psychic and somatic symptoms may closely resemble those of a melancholia attonita. The disorder terminates in chronic delusional dementia of a paranoiac cast, in rare instances in recovery, or in death, the last occurring with notable frequency from tuberculosis.

It is therefore a species of *folie circulaire* plus catalepsy, or a circular insanity in which one stage is a melancholia attonita. Kahlbaum and his supporters would regard it as a clinical and pathologic entity, having its characteristic symptoms and pathologico-anatomic findings, but the majority of alienists who have expressed themselves upon the subject, while recognizing in the name a convenient designation for a rare and interesting group of symptoms, deny to katatonia the honor of a separate place in their schemes of classification, and look upon the affection as only one of several forms of a pathologically alternating mental state, and distribute the cases of katatonia among the allied and more commonly recognized forms of insanity—hysterical mania, secondary paranoia, circular insanity or melancholia attonita. Clinical study of the insane simply adds to the confusion. The few typical cases, exhibiting the procession of melancholia, mania, stupor with cataleptoid and convulsive states, verbigeration and mutism, present a very striking picture; but when one or more stages are, as is usual, absent, the matter of diagnosis is by no means plain; gradations from katatonia into a half-dozen other forms of insanity can be traced, and all of the symptoms of katatonia, mental as well as physical, have been noted, singly or in combination, in cases of insanity that cannot by any effort be twisted into the katatonic mould.

Kiernan states that two per cent. of the patients in the New York City Asylum at Ward's Island (males) some years ago were the subjects of katatonia. The proportion of such cases among the insane of Alabama, judging from the two thousand five hundred cases treated at the State Insane Hospital during the past eight years, is certainly very much less than this; in fact, only one very typical case (Case I) has been observed; admitting a liberal number of transition-forms, in which "one or more of the stages are absent," at most a dozen instances of the affection among our twenty-five hundred patients have been seen, and almost all of these could with equal justice be included among other varieties of insanity. Our one case exhibiting most of the characteristic mental and physical symptoms of katatonia, with several others illustrating the transition-forms spoken of, is herewith reported:

CASE I was a white woman, of neurotic heredity, a native of Alabama, without education, a laborer's wife. She married at twenty years of age, but had no children; after four years her husband

deserted her, leaving her destitute. Two months later, following a brief period of vague depression and fear, she passed into a state of melancholia, with persecutory delusions, suspicion, and irritability. Eight weeks after the mental disease was recognized she was placed in the insane hospital.

Her condition at that time was as follows: Height, five feet two inches; weight, one hundred and six pounds; hair brown; eyes gray; complexion fair. Circumference of head was 52.7; antero-posterior diameter, 18.7; transverse, 14.3 cm.; the ear-lobes were small and ill-shaped, the lobes rudimentary and completely attached: the teeth were regular, the palate well formed. There was no striking asymmetry of face or skull, but in the latter the lines of suture were prominent; a slight depression was noted in the region of the anterior fontanel, and there was flattening of the occipital region. The body was tolerably well nourished and very muscular. The heart was normal; the lungs normal, save for the presence of a few bronchial râles heard posteriorly, on both sides. The woman had a slight hacking cough, and a temperature of 99.2° The breath was offensive, the tongue coated. Examination of the urine was entirely negative in results. There was no anemia. The patient was confused, incoherent, fretful, cross, and easily irritated; she replied to some questions with fair intelligence, but paid no attention to others. Distinct delusions were not elicited, but her manner indicated dread and suspicion. She stared blankly into vacancy, picked at her clothing or at the walls, or walked aimlessly about. She took her food voluntarily and was not unclean in habits.

During the three months immediately succeeding her admission the psychic features of the case altered but little; the woman remained quiet and indifferent most of the time, but when interfered with would rouse up, curse or scream, and occasionally strike anyone who happened to be standing near. There was a gradual failure in physical health during this time; fever was constant, and the patient lost flesh; she had a cough, with scanty expectoration of muco-purulent matter, in which a single examination failed to detect the bacillus tuberculosis. Physical examination of lungs was also without positive result, although the general symptoms were those of pulmonary tuberculosis in an early stage. At the expiration of about three months some improvement in the physical state was inaugurated; fever and cough disappeared, and the patient gained in weight and grew stronger. The mental symptoms also underwent a change in character, the depression, fits of reverie and abstraction gradually giving place to maniacal excitement; she became noisy, pugnacious, destructive, and very filthy in her habits; her talk was incoherent and usually abusive, but verbigeration was not shown. At long intervals during this period of excitement she would lapse into a state of stupor or reverie for a few moments, but when spoken to, would arouse and begin her noise and restless movement again. This continued for about thirteen months, her bodily condition remaining fair until toward the end of this time, when symptoms of tuberculosis reappeared, accompanied by a kidney-lesion, as shown by alternating diarrhea and constipation, headache, edema of the lower extremities and eyelids, and the constant presence in the urine of a small percentage of albumin, with many hyaline, granular, and nucleated casts, with disintegrating renal cells. As the physical weakness progressed, a change in the mental symptoms occurred, the heretofore almost continuous excitement resolving itself into violent maniacal outbursts, with intervening periods of quiescence, these gradually becoming of longer duration and assuming more and more the character of stupor. While in the stuporous state she would remain immovable for minutes or hours, and would not respond to questions. If taken hold of and compelled to change her posture, she would rouse up and curse, abuse, scream, and occasionally attempt to fight, after a short time relapsing into a condition of apathy. As the state of stupor deepened and grew more continuous, it was observed that her limbs retained the posture given them, and in a short time she exhibited a very typical condition of catalepsy; her muscles offered no resistance to movement, but held the limbs and trunk in any position in which they were placed; she would sit or stand for hours as impassive as a graven image, staring before her, but seeing nothing. The explosions of excitement became of briefer duration and rarer occurrence, and finally ceased altogether; after this she would remain quiet and immovable for days together, persistent mutism accompanying the stupor. During all this time emaciation was slowly progressive; she had a constant rise of temperature, reaching at times 102.5°; had night-sweats, diarrhea, a hectic flush on the cheeks, cough (occasional only, and very slight), scanty muco-purulent expectoration, in which, after several failures, the bacillus tuberculosis was detected. The physical signs of tuberculous disease of the lungs were in the beginning very few and inconclusive; dulness would be well shown at one examination, only to disappear entirely within twelve hours, and the abnormalities of respiratory sounds showed many variations from time to time. Cavities were detected toward the close.

After the woman became helpless and lay abed, she would remain in one position until moved by the nurse; she seemed almost devoid of sensation; the flies crawled over her face and into her open eyes and mouth unmolested and unnoticed; pins thrust through her skin called forth no evidence of pain; she exhibited almost no sign of life, save in her feeble heart-action and shallow respiratory movements.

The disease reached its inevitably fatal termination six months from the time of the return of tuberculous symptoms, two years after the onset of insanity.

This case offers an example of a fairly typical katatonia, but fails to illustrate the "verbigeration" that Spitzka in his definition makes an essential feature of the disease, and that Kahlbaum would regard as the most characteristic single symptom. The woman undoubtedly had tuberculosis at the time she was brought to the hospital, the accompanying

mental state being depression with a tendency to stupor; a remission or recovery from the tuberculous malady marked the maniacal period, and the return of the tuberculosis, with its steady progress toward a fatal termination, characterized the period of stupor and mutism, with cataleptic states.

The pathology of katatonia involves some considerations of especial interest. It seems undoubted that the scrofulous diathesis acts as a predisposing cause, if, indeed, it be not essential to the development of the disorder. Probably three-fourths of the fatal cases die of tuberculosis. Kahlbaum found in his post-mortem examinations many evidences of basilar meningitis and healed hydrocephalus. Kiernan, discovering similar lesions, draws the inference that a "basilar meningeal process of tuberculous origin" has existed in infancy.

Kiernan also found in one case a condition of mild sclerosis of the spinal cord and anterior pyramids, approximating in character senile sclerosis, and suggesting a possible connection between this lesion and the motor symptoms of katatonia. A somewhat marked opacity of the pia-arachnoid in the region of the Sylvian fissure and Broca's center, noted in many cases, has been assigned as the pathologic basis of the abnormalities of speech. These claims must be regarded as not yet fully proved.

Other appearances noted have been: passive venous engorgement of the vessels of the brain and pia; gelatinous exudate into the meshes of the pia-arachnoid; exudations upon the inner surface of the dura; exudation of "mucoid substance" upon the floor of the fourth ventricle; accumulations of lymphoid cells in the perivascular and pericellular spaces; pigmentation of pyramidal cells. In the later stages of the disease, *i. e.*, when dementia has become well established, there is atrophy of the convolutions, as is frequent in the late stages of many other forms of mental disorder.

All of the pathologic changes mentioned have been discovered, singly, or combined in various ways, in other forms of insanity, and characteristic lesions in katatonia have not yet been demonstrated.

The results of post-mortem examination in the case under consideration resulted as follows:

Autopsy, four hours after death. Emaciation was extreme, the weight of the body being about fifty pounds. Rigor mortis was entirely wanting.

The scalp was thin, the hair scanty. The antero-posterior diameter of the skull was 18.0; the transverse, 13.9; the circumference, 51.2 cm. There was no visible asymmetry; the bone was of medium thickness and soft; the sutures were mostly open; the diploë thin and red; the inner table pale, deeply grooved, and pitted. Small blood-coagula were found in the longitudinal sinus. Underlying the dura, on the left side, was a soft, friable, deep-red membrane-like blood-clot; the clot was evidently a recent one, and adhered very slightly to the inner surface of the dura; it measured about one-sixteenth of an inch at its thickest part; it covered almost the entire convexity of the left hemisphere, thinning out at the edges, where it lost its blood-clot character, and seemed continuous with a pale-yellow, very thin, and soft membrane, which extended a short distance beyond the blood-clot in all directions. The right half of the dura was free from disease. The dura at the base of the brain showed no evidence of existing or of former disease. The pia was thickened and edematous over the entire vertex, and opalescent along the lines of the larger bloodvessels and fissure of Sylvius. On the left side of the vertex it was deeply stained where it had lain in contact with the hemorrhagic clot, and near the anterior extremity of the interparietal fissure there was an extravasation of blood into the sub-arachnoid space. The pia at the base, and its various laminæ, were normal in appearance. The arteries of the base of the brain—the circle of Willis and its branches—showed no lesion or abnormality of anatomic disposition. The weight of the right hemisphere of the brain was 18¼ ounces; of the left, 18¾ ounces; of cerebellum, pons, and medulla, 5¼ ounces=42¼ ounces, the pia attached. Some atrophy was apparent in the gaping gyri and shrunken convolutions of the anterior lobe and motor area. There were no abnormalities of gyral arrangement worthy of mention. The brain-tissue was softish and watery; the gray layer was pale; the puncta vasculosa few; the lateral ventricles were large, and contained a little fluid; the ependyma and choroid plexus were normal. The basal ganglia, the pons, the medulla, and cerebellum exhibited no lesion.

The spinal cord was not removed.

The fat panniculus was absent from the thorax. The muscular tissue was atrophic, the costal cartilages unossified. The ribs and sternum were soft and fragile, bending easily, and seemed in great part lacking in inorganic salts; the ribs were readily cut with a knife. Upon firm compression a reddish semi-fluid mass could be made to exude from the cut ends of the bones. The precordial space was small. The pericardium showed no signs of disease. The heart was soft, pale, and relaxed; the superficial vessels tortuous; no atheroma or other disease was visible to the naked eye. External deposits of fat were not present. The muscular tissue was pale. All of the cavities contained soft, dark clots, and in each ventricle was a firm fibrinous clot which extended some distance into the aorta and pulmonary artery. There was no lesion of the valves. The aorta contained a few pale-yellowish atheromatous spots. The weight of the heart was 5½ ounces.

Old, firm adhesions existed at the apex of the right pleural cavity. Little or no fluid was present, and no signs of recent disease. The right lung was soft, pale, and edematous; there was slight anthracosis; all the lobes contained scattered tuberculous nodules, most numerous in the upper lobe. The nodules were small and cheesy. No cavities or areas of consolidation were found. The bronchi

seemed normal. The weight of this lung was 10 ounces.

Old adhesions were present throughout the entire extent of the left pleura; there were no recent adhesions or signs of disease. There were cavities in both lobes of the left lung, containing very offensive purulent matter; two or three cavities were nearly an inch in diameter; there were numerous smaller ones, many cheesy nodules, and, especially in the lower lobe, extensive patches of consolidation. Some of the smaller bronchial tubes were surrounded by caseous masses.

The bronchial lymph-nodes were filled with tuberculous nodules and anthracotic masses.

The peritoneum showed no lesion. The spleen was small, soft, and dark-colored; the capsule thin; its weight was 2½ ounces. The liver was dark, well filled with blood, and relaxed; its weight, 29 ounces. The gall-bladder was nearly empty. The right kidney was firm, pale, and small; the capsule slightly adherent, the cortical substance thin, pale, and the striæ indistinct; the pyramids were also pale, the boundary-layer a little darker in color; weight, 3 ounces. The left kidney weighed 3¼ ounces, otherwise resembling its fellow.

The supra-renal bodies were small, pale, and firm. No gross lesions existed. The stomach and intestinal tract were free from disease. There were no tuberculous ulcers or nodules in the small intestine, and the mesenteric glands were normal. The abdominal aorta showed some yellow splotches of atheromatous disease.

The ovaries were small, white, and scarred; the uterus, tubes, and ligaments were normal. The bladder was empty and without lesion.

Sections of the kidney studied microscopically showed irregular thickening of the capsule; bands and patches of interstitial thickening, with numerous round cells; some of the bloodvessels had thickened walls, some were tortuous. The Malpighian tufts showed an increase in nuclei, and proliferation of the cells lining the capsules; some of the tufts were entirely destroyed. The epithelial cells in the convoluted tubules were very granular and showed some disintegration; some tubules were entirely choked with débris, some contained casts. In the left kidney several small tuberculous nodules, with giant-cells, were discovered. The sections from the right kidney showed no cheesy nodules. With this exception the minute appearances of the two organs were very similar.

Preparations made from the dura and the underlying clot exhibited practically no lesion of the dura; the delicate film extending beyond the edges of the clot was composed of lymphoid cells, a few red blood-cells, and fibrin-shreds, held together by a homogeneous gelatinous material; it contained no capillaries. Between the blood-clot and the dura, this layer, if it existed, could not be detected; what was seen was a normal dura, and lying against its inner surface, a mass of coagulated blood; the delicate film referred to, and the mass of blood-cells of the clot seemed to merge into one another at the periphery of the clot. There was no evidence of inflammatory change in the dura, and no newly-formed bloodvessels were detected in the clot anywhere.

Aside from the tuberculous disease of the lungs, the nephritis, and the sub-dural hemorrhage, the autopsy was negative in result. The basal dura was smooth and to the naked eye of normal appearance; the pia covering the base, its extensions, and that portion in the region of Broca's center, were not noticeably affected. The brain and its membranes showed no peculiar or characteristic change.

The hemorrhage beneath the dura affords an instance of "pachymeningitis interna hæmorrhagica." In this instance, as in the other cases discovered in our post-mortem room, the effusion of blood would seem to be the primary lesion, the very insignificant changes present in the dura occurring as a consequence of the irritation of the extensive blood-clot. Sub-dural hemorrhage is not of rare occurrence among the insane. We have found fourteen instances in 142 autopsies—nearly 10 per cent.

The next case, while less typical than the one already reported, is still markedly katatonic in character. There is, however, no stage of exaltation, no verbigeration; the cyclic changes are confined to exacerbations of melancholia, with stupor and catalepsy, with intervals of partial recovery, terminating in delusional dementia.

Case II was a minister of the Methodist Church, of neurotic heredity, unmarried, of a liberal education; lues and alcohol were excluded. At the age of twenty-seven he had an attack of mental disorder of a melancholic character, recovering entirely and resuming his clerical work after a short time. Four years later he had a sudden and unexpected return of mental disorder—he was preaching, suddenly stopped short, bowed his head upon his hands, and remained immovable; he was taken from the church by his friends, and found to be in a cataleptic condition, and mute. After several months of stuporous melancholy with persistence of the cataleptic state, he was placed in the insane hospital. After four months a slow improvement began, and within twelve months he was comparatively well and talked readily and rationally; he was quiet, able and willing to work, and his physical condition was better; some vague religious delusions persisted, with occasional cataleptoid seizures. He remained unchanged for five years, and was then taken home by his family; but, soon relapsing, he was returned to the hospital in much the same condition as when first admitted, although the stupor was less pronounced and the mental depression more active; he had made one attempt at suicide while at home. He continued melancholic, hysteric, nervous, and emotional, with fits of reverie and cataleptic immobility, for some months; he exhibited religious delusions, and received commands from heaven; he occasionally refused food; and had periods of mutism of varying duration. After a time the active depression subsided; he grew less emotional and

nervous; the cataleptoid symptoms became less prominent; and his bodily state improved. He has never recovered; his present state (fourteen years after the first appearance of the insanity) is one of secondary paranoia, with fixed religious delusions and some dementia; at long intervals there are some cataleptoid manifestations; he is quiet and harmless, and talks readily and coherently. Physically he is spare and somewhat cachetic in appearance. He has an organic heart-lesion; casts and albumin are found in his urine; there is some arterial hardening, but no symptoms of tuberculosis. The case is hopelessly chronic.

The third case is one of melancholia attonita, with mutism and cataleptic symptoms. The cyclic feature is wanting.

Case III was a white man, a peddler, married, with limited education. The family history could not be obtained. At the age of thirty, having previously exhibited no eccentricity or intellectual weakness, he suffered a series of financial and domestic misfortunes; grew nervous and despondent, and eventually passed into a condition of acute melancholia, with delusions of suspicion and persecution, rendering necessary his commitment to the insane hospital.

The active melancholic symptoms soon gave place to a state of melancholic stupor, attended with cataleptoid manifestations. He lay in bed for months, would not speak, would not eat, was utterly inert and passive. He had one epileptiform convulsion four months before his death. He was fed through the stomach-tube for three months; and finally died of marasmus eighteen months after his admission to the hospital. There was no autopsy.

Case IV is even less typical. It is a simple primary confusional insanity, with catalepsy:

Case IV was a negro man, a laborer, without education, and unmarried. Signs of the insane constitution were marked. The family history was unobtainable. When nineteen years old the man had typhoid fever, followed by mental weakness taking the form of acute dementia and slowly increasing in intensity; after the stupor was well established, cataleptic symptoms appeared, and in this condition, which might be described as a "primary dementia, with catalepsy," he was admitted to the insane hospital. His condition has not changed materially since that time (sixteen months). He sits immovable, refuses to speak, will not go to his meals or make any attempt to take his food, until with plate before him and knife and fork in hand he is given a few mouthfuls by the nurse; he then finishes his meal unassisted. The cataleptoid states are well marked, but occasionally the man will change his position voluntarily. He comprehends perfectly, and, even when in a state of cataleptic immobility, watches sharply what is done by others near him, following with his eyes all movements made. There is no depression or exaltation, no cyclic changes whatever; he has not spoken since his admission.

His physical health is poor. His urine contains albumin and tube-casts, and there are some symptoms of tuberculosis.

In Case V we have many of the symptoms of katatonia, associated with exophthalmic goiter:

Case V was a white female, of a slightly neurotic, but unusually intelligent family, liberally educated, quick-witted and vivacious, and with some signs of the insane constitution. At the age of nineteen her previously recognized nervousness and hysteric tendencies became more marked, and were accompanied by cardiac palpitation and circulatory disorders; soon an enlargement of the thyroid gland, with exophthalmos, made itself apparent, and in time a typical picture of exophthalmic goiter was presented. The action of the heart was irregular and feeble, and at times very rapid—approaching two hundred a minute; there was much vasomotor disorder, with cyanosis of the skin and profuse sweating; dyspeptic symptoms, irregular and scanty menstruation, with a condition of general mental instability, also existed; the woman was moody, fretful, had fits of passion, and often grew angry with her relatives and friends, and made most unreasonable requests. She had frequent hysteric seizures; when at her worst, cataleptoid states were occasionally present.

About a year after the onset of the disease she had an attack of continued fever, resembling typhoid, which confined her to bed for several months and came near proving fatal. Two years later she had a similar, or, if possible, more severe attack, but again recovered, and then began improving in physical state; the goiter and exopththalmos slowly diminished, and she gained greatly in weight. There was, however, no change for the better in her mental condition; on the contrary, she became more irritable and more unreasonable, with exaggerated ideas of self-importance; she developed a fondness for social gaieties, spent money wastefully, dressed extravagantly, and sometimes fantastically; if crossed in any way she flew into a passion or had an hysteric attack, and at these times was markedly cataleptic. She ran away from home during the night on one occasion, and, after giving a great deal of trouble to her family, was finally sent to the insane hospital, seven years from the time the exophthalmic goiter was recognized. She then seemed in good health, with mental symptoms as sketched. She exhibited a great variety of symptoms during the succeeding three years, with a gradual failure in health and a steady passage into dementia. Her chief mental attitude was one of mild exaltation with a feeling of self-importance, a theatric and declamatory speech, which, based upon unusual intelligence and education, made a very interesting combination. At irregular intervals this excitement would give place to usually brief periods of hysteric melancholy, with marked cataleptoid symptoms; and she had two long periods of melancholia attonita, with occasional refusal of food and mutism, marked catalepsy and confinement to bed. The last of these covered the last months of the patient's life; she steadily emaciated, had a rise of

temperature, and diarrhea, night-sweats, and other symptoms of tuberculosis. She died at twenty-nine, ten years after she became insane. There was no autopsy. During the entire time of her stay in the hospital she exhibited the somatic evidences of Basedow's disease, in slight goiter, slight exophthalmos, tachycardia, circulatory abnormalities, and profuse sweating. Omitting the atypic initial stage and Basedow's disease, we have remaining in the alternating mental states, verbigeration, paranoiac exaltation, atonic melancholy, mutism, cataleptoid and hysteric conditions—a very characteristic katatonia.

Case VI was a white female, of limited education and neurotic heredity—her mother, brother, and sister being insane. Signs of degeneracy were marked. She married at twenty-two; a year later miscarried at the seventh month, and had a mild attack of what may be termed hysteric melancholia, but recovered after a month. Two years later she miscarried a second time, again at the seventh month, and passed into a state of atonic melancholy, in which, three months later, she was admitted to the hospital. She at first exhibited some persecutory delusions, but stupor soon became the most prominent symptom. She lost flesh rapidly. On admission she was in a state of complete and typical "melancholia with stupor," sitting for hours in one position, staring vacantly, the saliva running from her mouth. She would not speak, neglected to eat, to attend to calls of nature, etc. Her limbs offered a passive resistance to movement, and preserved for a short time any position given them, though cataleptic symptoms were never pronounced. She was thin, very pale, and anemic. The hemoglobin was estimated at 20 per cent., the red corpuscles at 3,214,000 to the cubic millimeter. Albumin and casts were found in the urine, and there was edema of the feet, legs, and face. There was cyanosis of the hands and general sluggishness of the circulation. There was an anemic heart-murmur, but no lung-complication and no fever. Put in bed, she lay passive and immovable. Tr. ferri chloridi was given. Food was administered with a spoon by a nurse. The patient had at times nausea, vomiting, and diarrhea. After three months the hemoglobin had risen to 62 per cent., and the red corpuscles to 4,212,000, albumin and casts being still present. She became less demented and would eat voluntarily, and reply to questions. She continued slowly to grow better in mental state, and got out of bed and gained flesh. After about twenty months she had an attack of excitement and irritability, and was very violent and pugnacious for a few weeks; she then became quiet and went into a second period of melancholia with stupor, with partial cataleptic states, circulatory sluggishness, and mutism. This passing off left her in a state of "secondary paranoia," *i. e.*, she was perfectly quiet and conversed rationally most of the time, had a good memory, and gave little indication of mental disorder, save for her fixed and systematized delusions and occasional slight exhilaration. She has, since she recovered from the last attack of melancholy, gained a great deal in weight; the hemoglobin has risen to 82 per cent., the corpuscles to 5,112,000. The urine still shows an occasional cast and a trace of albumin. The mental aberration is now of about three years' standing and will probably persist in some form.

In addition to the cases here sketched we have had probably as many more that exhibited cataleptoid symptoms in some form, but were in other respects even less typical of the condition under consideration than Cases III, IV, and VI. Including all of these as katatonia, the proportion of such cases, as already mentioned, is still very small—not more than half of 1 per cent. of our insane population.

INDUCED LABOR AS RELATED TO PUERPERAL ECLAMPSIA.[1]

By H. C. RIGGS, M.D.,
of Brooklyn, N. Y.

The work of modern investigators into the pathogenesis of eclampsia is only less remarkable for its painstaking labor than for its inadequate results. The theories deduced are almost as many as the writers deducing them. But in spite of this diversity of theory and conclusion there is discernible a tendency to agreement upon certain points of the most vital clinical importance.

It is probably fair to say, then, that modern opinion inclines to consider eclampsia as due to an intoxication either from retained body-excreta, or from the direct presence of microörganisms or their ptomaïns in the circulation; the elimination of both excreta and ptomaïns being retarded or prevented either by the simple renal congestion of pregnancy or by any coexisting form of kidney-lesion. If this be a proper statement of our present position, the supreme causative importance of the pregnant uterus as an etiologic factor becomes immediately evident. The uterus as it enlarges interferes in a greater or less degree with the circulation in the abdominal viscera and in the lower extremities. Varices of the rectum and limbs, constipation, vesical irritation, polyuria, albuminuria, are well-marked evidences of the mechanical results due to increased abdominal tension from the enlarging uterus. This congestion is, in the majority of cases, well sustained by the organs during the time of gestation, and disappears, leaving no trace when the fetus is expelled and the uterus returns to its normal size and position. But in a certain percentage of cases, fortunately small, serious consequences remain, especially in the kidneys. These are:

a. In previously healthy kidneys the usual con-

[1] Read before the Kings County Medical Association, December 12, 1893.

gestion may become so severe as to prevent their free action.

b. The kidneys may pass beyond simple congestion into some one of the forms of structural renal lesion.

c. A previously existing nephritis may be aggravated in character and intensity.

It is in some one of these three classes that we find most of our cases of eclampsia. In saying this we have to recognize that there is a certain small group of eclampsias not to be included in such a classification, namely, those classed by Dührssen as "eclampsia reflectoria," in which the symptoms seem to be produced by peripheral irritations acting upon hyperesthetic nerve-centers. But leaving out this small group our original classification holds good and we are forced again to perceive the important relation of the pregnant uterus to the causes of eclampsia. This is further made plain by the fact that in 93 per cent. of eclamptic seizures the symptoms subside upon the removal of the fetus and the contraction of the uterus.

With these points in mind let us proceed to consider, very briefly, the modes of treatment at our command, and their applicability to the conditions which confront us in this class of cases. It will be convenient in discussing the subject of treatment to divide it into two parts: 1. The treatment of cases occurring before the child is viable. 2. The treatment of cases occurring after the child is viable.

Let the first class include all eclampsias occurring up to the end of the sixth month of gestation.

The problem here presented is threefold: 1. The preservation of the mother's life. 2. The retention of the living fetus *in utero*. 3. The relief of the convulsive symptoms and the prevention of their recurrence. Without going into details, as it is my purpose especially to discuss cases coming under the second division of the subject, we may probably best attain these ends by prompt resort to anesthetics and other sedatives, such as chloral and morphin; and then by the use of diuretics and diaphoretics such as hot blankets, hot air baths, pilocarpin, and nitroglycerin. All other remedies failing, rapid dilatation of the cervix and emptying of the uterus are justifiable, but should probably be regarded as a last resort.

Our second class includes those cases occurring between the end of the sixth month and full term. Here the indications to be met are the same as before. But we have now a new factor to deal with, *i. e.*, a living fetus *in utero* capable of continuing its life not only in the uterus, but out of it. The term "viable" as here used is of course relative. Fetal viability varies greatly within the limits of the so-called viable period. It increases rapidly in degree through the eighth month, and more slowly during the first half of the ninth, so that during the last two weeks of gestation the child is almost as well adapted for independent existence as at full term.

Now with this factor of fetal viability added, what is the best solution of the therapeutic problem presented? Along what line may our treatment advance, with the best results to mother and child in the greatest percentage of cases?

The answers to these grave questions cannot be unanimous. No medical question can be answered in that way. But professional opinion, it seems to me, is more and more converging upon prompt induction of labor as the procedure which best meets the conditions of the problem. We need not stop to say that other methods of treatment now in vogue are far from satisfactory. This is universally admitted.

The advantages of this operation are its speed of execution and its effectiveness of action in relieving the eclampsia and in preventing its recurrence.

The objections to it are: 1. Possible destruction of a fetus that might have a chance of life if less radical means were used. 2. Risk of death to the mother either from shock or sepsis. Let us consider these objections in the light of modern statistics and see whether the danger to fetal and maternal life is increased, or whether it is diminished by this procedure.

First as to the maternal mortality from induced labor:

Dr. McLane, in reporting the first thousand deliveries at the Sloane Maternity, notes 12 cases of premature labor for contracted pelvis, with no deaths of mothers.

From the Dresden Clinic there are reports of 45 induced labors with only one death of a mother.

Wyder, of Berlin, notes 306 cases with a maternal mortality of 3.9 per cent.

In his little book on *Practical Midwifery*, Reynolds says: "Prognosis of induced premature labor should differ but little from the prognosis for labor at term, as far as the mother is concerned."

The cause of death in most of the cases quoted is septic poisoning. As these deliveries were performed chiefly for contracted pelvis the danger of sepsis was greater, owing to the unavoidable traumatism and pressure from the instruments; so that with reasonable care statistics should bear out the statement of Reynolds exactly, when the operation is done for eclampsia, when the child is smaller than at term, and the pelvic diameters are normal.

It is fair to say, in view of these facts, that considered merely as a therapeutic agent this operation is hardly more dangerous to the mother than many of the well-accredited drugs which we use with more

or less frequency in eclampsia. Pilocarpin and veratrum, chloroform and morphin, all occasionally claim their victims. Few drugs and fewer operations can be called absolutely safe. So with this operation, it is not devoid of risk, but the risk sinks out of sight in face of the unspeakably greater dangers of the condition we seek to relieve.

Secondly, as to fetal mortality from induced labor. This phase of the question has always been the one upon which opinions have differed most radically, as regards both its medical and its moral aspects. It is upon this side of the question, too, that statistics have been most unfavorable.

But even here, time and careful work and improved technique are doing much to reduce the prohibitive figures of former years. The earlier in the viable period the operation is performed the less satisfactory are the results as regards the life of the child. Tarnier's methods of care for premature children have done much to improve the statistics. He reports a death-rate of 36.4 per cent. in seven-months cases and of 14.3 per cent. in eight-months cases. Of course, these results are obtained in hospitals in which the facilities for caring for the children are of the very best. But I think it can be claimed that a reasonable approximation to these figures may be reached in private practice, if the persons caring for the child are of ordinary intelligence and are properly instructed by the physician.

Then, too, we have to remember that the conditions for which premature labor is induced are in themselves very dangerous to the fetus, as well as to the mother, for whose sake the operation is usually done.

In eclampsia, for instance, children are born dead from asphyxia or other causes connected with the systemic condition of the mother in a very large percentage of cases. Actual statistics on this point seem rather inaccessible, but a comparison of many estimates places the fetal mortality in antepartum eclampsias at about 30 per cent.

And now let us sum up what we have tried to present in favor of induced labor, considered merely as an operative procedure, without reference to its applicability to particular classes of cases. We find it to be:

1. An operation of simple technique which may produce its results rapidly or slowly, as may be desired.

2. An operation whose mortality for the mother is relatively and actually low—little, if any, greater than that of natural labor.

3. An operation whose fetal mortality is actually high, but which progressively lessens as the period of fetal viability approaches full term.

Finally, let us see how the features of this operation square themselves with the therapeutic problems presented in the treatment of eclampsia. By the terms of the operation we exclude consideration of all cases in women less than seven months pregnant, for such an operation before the seventh month is more properly termed an abortion; and we also exclude in the same way cases occurring during or after spontaneous labor. We will consider the applicability of the operation to these cases, first, as a direct remedial measure, and, secondly, as a prophylactic measure.

1. In the presence of eclamptic convulsions delay amounts almost to malpractice. After controlling the reflexes by sedatives our duty, it seems to me, is the immediate use of the most effective and most rapid remedial agent to be had. We have shown that convulsions cease in 93 per cent. of the cases as soon as the uterus is empty. We have shown that the maternal mortality is practically nothing from this operation, which will promptly empty the uterus. We have shown that the fetal mortality of induced labor, while high, is less than the fetal mortality from eclampsia, in all but the earliest part of the viable period. We have shown that the operation is simple and may be completed very rapidly.

These facts seem to demonstrate that the induction of labor is the most efficient and at the same time a reasonably safe operation in these cases.

In view of this demonstration and in view of my own experience, which, while not large, has been terribly instructive; and in view of the experience of a growing number of my professional brethren, I advocate most strongly the immediate induction and termination of labor by means of manual dilatation and extraction of the child by forceps or version. And I wish to be understood as advocating it not as a procedure of last resort but of first resort, a procedure not of necessity but of election.

The difficulty in applying this operation as a prophylactic against eclampsia lies in the vagueness of the premonitory warnings of the approaching convulsions. Most of the important signs of an attack are those which we commonly associate with uremia.

There are many good authorities who consider that induction of labor is not only justifiable but necessary in the presence of edema and albuminuria, which become constantly worse under proper treatment and diet.

Lapthorne Smith (in a note to the *Medical Record* of October 28, 1893) says: "In fact, I have gone so far as to hold that it was our sacred duty to terminate every pregnancy as soon as we discovered that the urine was loaded with albumin, for if we allowed this state of affairs to go on too long the kidneys might become irretrievably injured."

Minor premonitory symptoms, such as frontal headache, epigastric pains, uncertain vision not accompanied by urinary changes, if they do not in themselves constitute an indication for inducing labor, should at least serve to put us on our guard and in readiness to operate at a moment's notice.

Of course, the question of inducing labor as a prophylactic becomes a new question in each case. Only a survey of all the facts can determine for or against it. Prof. T. G. Thomas, in his lectures on Abortion, says: "I would say incidentally that I often induce premature labor, and I regard it as a procedure of the greatest possible importance. With the experience which we now have, it can only be regarded as trifling with a woman's life to allow her to go to full term in cases of aggravated albuminuria from puerperal nephritis."

As to the prophylactic use of this operation my contention is that it is practicable, legitimate, and effective within the limits which we have just laid down.

I am aware that the facts and conclusions I am presenting are not new. With the added weight of great names and great experience they have been stated far more clearly and more powerfully than I can hope to state them. But they have not yet become the fixed law of procedure in the profession at large. Iteration and reiteration is the necessity in promulgating a matter of this kind. And it is in the hope of obtaining for it the weight of your assent and the power of your personal example that I have ventured to open this subject before you for discussion this evening.

Statements and Facts to which Physicians cannot Testify.—In an action to recover for personal injuries, a physician cannot testify as to statements made to him by the party suing, when the latter calls on him after the suit is brought in order to give him such information as will enable him to testify as an expert at the trial. Neither can he testify as to the nature of an internal injury received six months before, and which has since been healed. So holds the Supreme Court of Errors of Connecticut, in the case of Rowland *vs.* Philadelphia and Baltimore Railroad Company. In this case the witness had been told by the party that his ribs had been broken, but had healed. With regard to this, however, it was held that he could not testify for either of the reasons given.

ORIGINAL LECTURE.

TUMOR OF THE BRAIN SIMULATING A VASCULAR LESION; TO WHICH IS ADDED AN ACCOUNT OF THE AUTOPSY, WITH REMARKS.[1]

By J. T. ESKRIDGE, M.D.,
of Denver, Colorado;
Professor of Nervous and Mental Diseases in the Medical Department of the University of Colorado; Neurologist to the Arapahoe County and St. Luke's Hospitals.

The case which I wish to study with you to-day is of especial interest, because the most obtrusive symptoms point to an entirely different lesion than the one from which the patient is suffering.

Michael P. K., twenty-seven years of age, of New York, a waiter, single, white, living in Colorado for the past seven years, was admitted into the nervous wards of the hospital about 2.30 P.M. yesterday in a semi-conscious condition. His temperature was 98.4°, the respirations 22, and slightly stertorous when he was not aroused; the pulse full, and 64 per minute. The resident physician does not know whether any paralysis was present at the time of his admission or not, as he did not make any examination to determine the point. During the afternoon, owing to the kind perseverance of the nurse, she succeeded in arousing him sufficiently to get some points in his history. He came of a family of hard drinkers, and he had five brothers, all of whom indulged freely in the use of alcohol. The patient stated that he had always enjoyed good health until about six months ago, when he contracted a severe cold. Since then he has not been very well; at times he has felt all right, and at others he has complained of a numb pain in the head, and a confused sensation, which prevented his thinking connectedly.

It was ascertained from his acquaintances that up to the time of the occurrence of his present trouble he had been occupying a room in a lodging-house, and nothing wrong was noticed by any of the lodgers until yesterday morning, when he arose, apparently as well as usual, and began to dress himself, but before he had completed his toilet he fell to the floor. When found, a short time afterward, he seemed confused and was unable to rise.

At the time of my first visit, at 8 P.M., a few hours after his admission into the hospital, he was lying quietly and sleeping, but his respiration was slightly noisy when left to himself. His temperature was normal, and equal in each axilla, the pulse 72, and rather full and strong. He was easily aroused from his stuporous sleep, and for a few moments seemed to realize what was said to him; but if left alone, he immediately relapsed into an apparently unconscious condition. His left arm and leg were almost completely paralyzed; the face was apparently unaffected, and he protruded the tongue in the median line. Sensation seemed to be normal. The right knee-jerk was slightly increased; the left a little greater than the right. The plantar reflexes were absent, and no ankle-clonus could be elicited. The cremaster and abdominal

[1] A Clinical Lecture delivered at the Arapahoe County Hospital, Denver, Col.

reflexes were slight on the right side and absent on the left. The pupils were equal and widely dilated, but reacted slightly to light. There was no paralysis or paresis of the external ocular muscles. On examining the fundi of the eyes a condition of bilateral optic neuritis was found. The disc was more swollen in the right eye than in the left, but the latter had reached a more advanced stage, and presented distinct atrophy of the optic nerve, with arteries very small. The other special senses, so far as I was able to determine, were normal. The urine was free from albumin and sugar, and the lungs seemed to be in a normal condition. Headache was not complained of unless the man was aroused and asked about it, when he would say that his head pained, but his appearance did not indicate much suffering. His bowels were freely evacuated, and he slept during the night, unaided by a hypnotic.

His stuporous condition has deepened since my visit last night, and I have brought the patient before you to-day so that we may study his condition together, hoping that I may be able to bring out some points in connection with this case which may aid you, even in the absence of a history, in dealing with persons found in a state of partial or complete unconsciousness.

On reëxamining our patient to-day we find him in a condition very much the same as that in which I found him at my first visit some sixteen hours ago, with these exceptions: that the paralysis of the left arm and leg has deepened, so that their muscles are now nearly flaccid; that the left side of the face, from the nose downward, is slightly paretic; and that the state of stupor is rapidly passing into coma. You see that I cannot get any intelligent response from him. When I call to him he simply opens his eyes and moves his lips, and immediately sinks into a condition of blissful unconsciousness of his impending fate.

You must remember that a condition of partial or complete unconsciousness may be produced by syncope, from heart-failure; by chloral, opium, or alcohol poisoning; by uremia, epilepsy, or hysteria; or by an apoplectic state caused by apoplectiform attacks occurring in cerebral congestion or paralysis of the insane; by "simple apoplexy" in the aged, or by apoplexy from embolism, thrombosis, abscess, cerebral hemorrhage, or tumor of the brain.

You see, then, that we may have a more or less sudden disturbance of consciousness, from perversion of brain-function, and that this may be due either to direct or indirect causes acting upon the brain. In some cases of suddenly induced unconsciousness, even from structural brain-disease, there are but slight, if any, localizing symptoms, so that, in the absence of a consecutive and reliable history, you may at times be sorely puzzled to determine the cause of the unconsciousness. When persistent paralysis exists, especially if it is associated with optic neuritis, all such general causes of unconsciousness as syncope from heart-failure, chloral, opium, alcohol, and uremic (?) poisoning may be excluded. The bilateral optic neuritis, excluding lead-poisoning, uremia, and profound anemia, is positive proof that the trouble is organic, and therefore hysterical and epileptic coma, as well as "simple apoplexy," may be disregarded in the diagnosis of the lesion in the patient before us.

Having excluded all causes, except those of an organic nature, to which of the numerous organic brain-lesions may we attribute this man's condition?

For diagnostic purposes, these lesions may be divided, as regards the time consumed in their development, into sudden, acute, and chronic.

The sudden lesions are vascular in their nature, and are due to embolism, thrombosis, or cerebral hemorrhage. You must all realize the importance of a consecutive and reliable history of the patient prior to the development of the prominent symptoms of the disease, and an intelligent account of the mode of invasion of the disease. In the absence of such a history it is sometimes utterly impossible to make a diagnosis. With the light which a reliable history throws on a case, positiveness in differential diagnosis may be obtained by careful analysis and comparison of all the symptoms. Unfortunately, in the history of the present case, the information is meager, and it is questionable to what extent it may be relied upon. Prior to the development of the paralysis yesterday morning but little is known, except that for the past few months the man found it difficult to think, owing to what he called a confused feeling in his head. Pain in the head was only complained of as a heavy sensation. When I first saw him he made so many contradictory statements that I was unable to learn whether he had ever had syphilis. He was not seen until several minutes after he fell on the floor while dressing in the morning, and when found he was unable to rise and seemed stupid. He could give no account of this attack. It is fair to presume that the paralytic symptoms and mental confusion came on comparatively suddenly, although we must bear in mind that he might have gotten out of bed with impaired motility and mental power, and that these simply increased while he was trying to dress himself. In embolism there are usually no head-symptoms antedating the attack, and to justify the diagnosis of cerebral embolism we should be able to find a cause for the embolus, such as acute or chronic endocardial trouble. No such cause exists in this patient. In rare instances embolism gives rise to optic neuritis, but it is evident that this could not occur until several days had elapsed after the occurrence of the brain-lesion, so that we can exclude embolism in this case. Without going into a detailed account of the symptoms of thrombosis and cerebral hemorrhage, a consideration of these may be discarded in the diagnosis of our patient's trouble, as insufficient to account for the presence of optic neuritis, which does not arise from either of these vascular lesions.

You see, then, that a sudden or vascular lesion, although the paralytic attack was undoubtedly more or less sudden in its onset, will not account for all the symptoms which this man presents; I wish you to bear in mind, however, that while a vascular lesion will not account for all the symptoms, it would account for the rapid development of paralysis, and such a lesion may occur as a result of a more chronic malady and give rise to sudden symptoms, thus making a diagnosis, in the absence of a reliable history, exceedingly difficult. Of this I may have something to say later, in explanation of some of the symptoms presented by our patient.

The acute lesions of the brain are inflammatory in their

nature, and require from a few days to a week or more to reach their height. They are all, as a rule, attended with some rise of temperature and considerable headache. Whilst optic neuritis may appear early (fifth day, Gowers), atrophy, such as is found in the present case, is not seen until after the second week. So that normal temperature, absence of marked head-pain, the sudden onset of the main symptoms, a few hours ago, and the presence of optic neuritis, with beginning atrophy, enable us to exclude the acute organic brain-lesions.

We have left, to account for our patient's condition, which seemed on superficial observation to be due to some sudden lesion, one of the chronic organic brain-diseases. We can exclude the scleroses, and in the light of what history was obtainable at the time of the patient's admission into the hospital, together with the symptoms found on examination, we need to consider only two lesions, viz., tumor and chronic abscess.

The diagnosis between tumor and acute abscess of the brain is usually easy, but between tumor and chronic abscess it is sometimes most difficult, if not impossible, especially if we find ourselves laboring under the difficulties encountered in the present case, in which a reliable history and accurate observation of symptoms, prior to the sudden development of the apoplectic symptoms, are entirely wanting.

In chronic abscess there is usually the history of a cause of suppuration, such as chronic ear-disease, infective disease of the nose or of the bones of the skull, or suppuration in the lungs or elsewhere. In abscess of the brain one of these causes is found in about three-fourths of the cases. After the first disturbance, caused by the formation of pus, a latent period of several weeks, months, or years may follow, during which the patient may complain of slight or no brain-symptoms. The latent period is sometimes cut short suddenly by terminal symptoms resembling apoplexy, such as paralysis, convulsions, coma, and death.

Most tumors of the brain run a gradually increasing course, with decided head-symptoms, without a latent period, and with final symptoms in accord with the previous history of increasing gross organic brain-lesion. But we must remember that gradually-growing tumors in a portion of the brain, the destruction of which gives rise to no definite focal symptoms, may run a comparatively latent course, and finally bloodvessels may be encroached upon and occluded, giving rise to symptoms resembling thrombotic apoplexy. Again, in the course of tumor of the brain we may have the occurrence of a vascular lesion, in every way independent of the morbid growth. One such case was observed by me in this hospital about a year ago. The patient was suffering from a slowly-growing tumor attached to the dura on the right side of the brain, and a large hemorrhage occurred into the left corpus striatum and proved fatal in a few hours. The autopsy revealed advanced degeneration of all the large arteries at the base of the brain. The hemorrhage that sometimes occurs in the substance of vascular tumors rarely proves fatal.

Finally hemiplegia may occur in the course of brain-tumor, and death result; and the autopsy may afford no explanation of the suddenly-developed symptoms. Some years ago, Gowers (*Brain*, 1879, vol. i, p. 48) reported a number of cases of sudden paralysis occurring in the course of cerebral tumor.

The points in the case of the patient before us in favor of chronic abscess are: excluding a vascular lesion, as we have done already, terminal symptoms resembling apoplexy in a case of latent chronic brain-trouble, and optic neuritis.

Evidences in favor of tumor rather than abscess are: absence of a cause for the development of abscess (this is always a strong point against abscess); intense optic neuritis, as evidenced by considerable swelling of the right optic disc, and absence of rigor and fever, which so commonly attend the terminal stage of chronic abscess. All these symptoms, except optic neuritis, are negative ones in favor of tumor, but very positive against abscess.

The weight of the evidence is in favor of tumor of the brain, and I venture this diagnosis in view of the probability of being able to verify or disprove it by an autopsy in a few hours or days.

I wish to call your attention to the fact that, outside of gross organic brain-disease, renal trouble, lead-poisoning, and profound anemia will give rise to optic neuritis, but it has not been necessary to consider these, because of the positive evidence of a brain-lesion to account for the patient's condition, although, as a matter of fact, the urine is free from albumin, there are no evidences of chronic lead-poisoning, and the patient is not anemic.

Having made the diagnosis of tumor, is it possible in the present case to localize it? The base of the brain can be excluded, from the fact that the cranial nerves have not been affected; and the cortex of the convex surface is probably not the seat of the growth, in the absence of convulsions; and a growth in the cerebellum would not give rise to distinct hemiplegic symptoms, without interfering with the functions of the medulla or pons. In all these situations headache would probably have been a prominent symptom, and you remember that, on the patient's admission into the hospital, he stated that he had not suffered much from head-pain.

Excluding, then, these situations as the probable seat of the growth, we have left the centrum ovale in the right hemisphere. The growth did not have its origin in that portion of the centrum ovale occupied by the fibers of the corona radiata which connect the anterior two-thirds of the posterior half of the internal capsule with the cortical motor region, else paralysis would have been an early, instead of a late, symptom. The tumor has had its origin either anteriorly or posteriorly to the radiating fibers of the motor region, and these fibers have been encroached upon by a sudden extension of the morbid process to them. Whether the disease began anteriorly or posteriorly to the fibers of the motor region is not an easy matter to determine—especially so in the absence of a complete history. We learn that there was some difficulty in mental concentration for months, but this was not sufficiently marked to attract the attention of the man's friends. Lesions in the centrum ovale posterior to the radiating fibers passing to the motor region might run an almost completely latent course, but when the anterior lobe of the brain is the seat of tumor we should expect to find mental disturbance, such as apathy, inability to concentrate the mind, with,

probably, more or less moral obtuseness. In the present case, in the absence of a reliable history, I must confess that I am unable to make a more definite diagnosis as to localization than the centrum ovale of the right hemisphere.

In regard to the treatment of the present case little or nothing can be done. The patient is now comatose and he will not live more than a few hours, or a day or two at the most. It is too late to attempt to get the effects of medicine, and were we sure as to the exact location of the morbid process, the physical depression is too great to justify an effort for its removal by surgical means. I shall not discuss at length the probable nature of the tumor, but it is most likely syphilitic or gliomatous; although, as the patient dated the beginning of ill-health from a "cold on the lungs," it may be tuberculous. I will report further on this case at our next clinic.

(After the lecture the patient continued to sink into a deeper state of coma and died about twelve hours later.)

At the autopsy, made ten hours after death, by Dr. Axtell, in the presence of Drs. McLauthlin, Mack, and Hull, and myself, the brain only was examined. No abnormally firm adhesions of the dura to the bone existed. The sinuses and the veins of the dura were distended with dark, fluid blood. No clots were found.

The veins of the pia were everywhere filled with dark, fluid blood. There were no signs of inflammation of any of the membranes, and the pia readily stripped from the brain. The arteries at the base were empty and showed no evidence of disease. The left cerebral hemisphere appeared normal throughout. The centrum ovale of the right hemisphere, from near its posterior portion in the occipital lobe to a point opposite the middle of the fissure of Rolando, showed evidence of disease. This entire area was occupied externally by what appeared to be ragged brain-substance, some portions of which were softer than the normal brain-tissue, whilst others presented an increased resistance to the finger. The parts anteriorly and internally (toward the lateral ventricle) appeared quite soft. In the interior of this tumor-like mass was found, in one portion, one or two ounces of yellow, watery fluid, and in another, which was separated from the cavity containing the watery fluid by a portion of the growth, a sanguino-purulent gummy-looking material. Considerable of the yellowish, watery fluid was found in the right lateral ventricle. It is impossible to say whether this found its way there before death or during the dissection. Great care was used in examining the brain, yet, on account of the fluctuating condition of the whole of the posterior portion of the right cerebral hemisphere, a rupture of the wall of the lateral ventricle could easily have taken place. None of the fluid had gravitated to the fourth ventricle, making it probable that the fluid had escaped into the lateral ventricle during the dissection.

A microscopic examination was made by Dr. Axtell, whose report is appended.

The softened material surrounding the cavity containing the fluid showed nothing but granulation-tissue; no connective-tissue elements were found; leukocytes and red blood-corpuscles were found in abundance. It was simply softened, broken-down brain-substance.

Of the gummatous substance, a large amount of granular material, composed principally of granular leukocytes, and containing numerous red blood-corpuscles, was found. The hardened portion of the brain-substance posterior to the semi-liquid material showed the usual appearance of gummatous infiltration.

With the additional light which the autopsy revealed in the foregoing case, a few points can be more intelligently discussed now than during the patient's life. What was the cause of the sudden and grave symptoms and the speedy death? What part did suppuration play in this man's case; was it primary or secondary? Do not syphilitic growths infiltrate the surrounding brain-tissue?

It seems to me that the extensive softening and hemorrhagic infiltration, which were undoubtedly of recent date, prior to the syphilitic growth, and involving the coronal fibers going from the internal capsule to the motor region of the brain, were sufficient to account for the sudden paralysis. It is probable that the liquid material, which, before the sudden breaking down of the brain prior to the syphilitic growth, had been enclosed in a circumscribed cavity, after the softening was allowed greater freedom of motion, and thus, by its pressure on the external wall of the lateral ventricle and on the great ganglia at the base, added to the shock already set up by hemorrhagic infiltration and brain-softening.

After the man's death it was learned that he had been under treatment for a number of weeks for supposed syphilis of the brain, prior to his admission into the hospital, and had taken potassium iodid during this time. The treatment accounts for the yellowish liquid found in the interior of the growth. I have observed, post-mortem, several cases of syphilitic tumor which had been treated by potassium iodid, and in most of these, especially when large doses of the medicine had been used, a considerable amount of a straw-colored watery fluid has been found. I have not seen this state of affairs in cases that have not received anti-syphilitic treatment.

What part did the suppuration play in this man's case; was it primary or secondary? So evident were the characteristics of pus found at the autopsy, that at first I was inclined to regard the case as one of chronic abscess; but the induration of portions of the surrounding brain-substance and the microscopic examination both showed the presence of a growth; besides, the pus was not of the distinct greenish color so commonly met with in abscess of the brain. Moreover, there was no odor to the pus-appearing substance. Since, then, it is not likely the formation of pus antedated the growth, it must have been secondary to it and in all probability due to the destructive process of the rapidly growing tumor. This is the first case of tumor of the brain in connection with which I have found pus. I see no reason, however, why we should not have the formation of aseptic pus from the acute softening that may take place as the result of blocking up of blood-vessels from the encroachment of a growing tumor.

The third and last question that I will consider is: Do not syphilitic growths infiltrate the surrounding brain-tissue? Gowers, in the second edition of his *Diseases of the Nervous System*, vol. ii, p. 493, under the heading "Syphilitic Growths," says: "The adjacent brain-substance is softened and more or less displaced, but it is not infiltrated by the growth."

On the other hand, Bramwell, in his work on *Intracranial Tumors*, p. 216, in quoting from Heubner on the appearances of syphilitic growths of the brain, says: "This form of tumor is never sharply defined; on examining the edges by the microscope, one may see at points apparently normal a strongly-marked cellular infiltration, which gradually passes into the healthy tissue."

Ziegler, *Special Pathological Anatomy*, sect. ix–xii, p. 311, beautifully illustrates diffuse cellular infiltration (syphilitic) of the cortical substance of the brain in a case of gummatous syphilitic meningo-encephalitis, and on page 312, after describing, in connection with this illustration, the tendency of syphilis of the membranes to involve the adjacent brain-substance, he states: "The same holds for the nodes which develop independently in the substance of the brain and cord."

Delafield and Prudden, in their work on *Pathological Anatomy and Histology*, in speaking of gummy tumors, to which they devote but a few lines, only refer to coagulation-necrosis and degeneration as taking place in the surrounding tissue.

In a case of syphilitic growth of the brain, operated on for me by Dr. Parkhill about two years ago, in a man about thirty years of age, a cavity containing about four ounces of a yellowish, watery fluid was found, and microscopically the brain-substance was indurated and softened around this cavity for some distance, making the size of the growth, from naked-eye appearances, four and a half inches in its longest dimensions, by three and a half and three inches in its shorter. The hemisphere of the brain from which this tumor was taken at the autopsy was examined by a competent microscopist and found to be infiltrated with gummatous tissue around the growth, even in portions which appeared macroscopically to be normal.

It seems to me that since surgical operative procedure is recommended for the removal of syphilitic growths, it is of the first importance to recognize the fact that these growths affect the surrounding brain-tissue, both by necrotic softening and gummatous infiltration, and that in many cases of long-standing tumors of this nature the brain-tissue has been so extensively infiltrated that but little or no good results can be reasonably expected after the excision of the old tumor-mass. I believe that Mr. Victor Horsley is right in urging early operation for the removal of syphilitic growths, if symptoms do not rapidly disappear under vigorous anti-syphilitic treatment.

CLINICAL MEMORANDA.

CASES OF LAMINECTOMY FOR SPINAL FRACTURE.

By JOHN B. ROBERTS, A.M., M.D.,
of Philadelphia;
Professor of Surgery in the Women's Medical College and in the Philadelphia Polyclinic.

The hopelessness of laminectomy for old vertebral fracture is well shown in the following cases, and in suspected fracture of the spine should serve to enforce upon us the vital importance of immediate operation for removing the displaced bone. While it is true that the damage to the cord and its membranes usually occurs at the instant the bodies or vertebral arches are broken, it must be remembered that the possibility of restoring function and limiting secondary inflammations and degenerations rapidly decreases with time. Hence the surgeon should operate as promptly in spinal fracture as in cranial fracture.

When there is doubt as to the existence of spinal fracture or dislocation it is good surgery to make an exploratory incision. If no osseous lesion is present such an operation performed aseptically will add little risk to the patient's life. If such lesion is present, prompt removal of pressure upon the cord holds out the only chance for restoration of its function. Often the damage to the nervous structures will be irreparable, but the patient has at least been given a chance. The risk, from hemorrhage (always severe in laminectomy) and from operative shock added to the shock of injury, will nearly always be justified by the danger to life and physical usefulness inherent in the original traumatism.

I am a believer in operation, even in cases of old fracture, because it offers the only possibility of effecting benefit. If aseptic it is accompanied by but a moderate risk to the patient's life. Unless it is performed the surgeon has failed to give the patient the benefit of every possible chance. Of recent articles on this subject, that of Dr. A. M. Phelps in the *Journal of Nervous and Mental Disease* for July, 1893, will be found interesting. I record the histories of a few cases.

FRACTURE OF THE SPINE IN THE DORSO-LUMBAR REGION SUBJECTED TO LAMINECTOMY THREE TIMES; NO IMPROVEMENT IN SYMPTOMS.

A man aged thirty-one, residing in Massachusetts, fell a distance of twenty-four feet in December, 1891. He states that he struck upon his heels and then upon the sacral portion of the back, which came in contact with railroad ties. I am indebted to Dr. C. C. Laffer for the following notes, taken from the records of the Methodist Hospital, where he was admitted in October, 1893.

The fall was immediately followed by loss of power and sensation in the lower limbs and of the body up to the level of the crest of the ilium, with loss of the control of the bladder and bowels. The contusion of the soft parts of the back was followed by a bedsore, which later healed.

Six weeks after the injury, twitching of the muscles of the toes was noticed, which later became manifest throughout the entire leg. Five months after the injury the man was operated upon, and laminectomy of the ninth and tenth dorsal vertebræ performed. Some depressed fragments of bone were removed. The cord was compressed into a narrow band and crowded forward; the cord appeared healthy, but the membranes were not opened.

After the operation the patient regained some sensation in the testicles, which he still retains. A second operation was performed five months later, the site being in the lumbar region. No bone was discovered pressing on the cord. After this second operation there was improvement in the condition of the legs, which previous to the operation were covered with bedsores. At the present time the patient feels well, has a good

appetite, digests food well, sleeps well, but is constipated. Urinalysis showed a dark-reddish color of the urine, a heavy yellow precipitate, an ammoniacal odor, an alkaline reaction, and a specific gravity of 1021, without albumin or sugar. Phosphates, pus, blood, and epithelium were found present.

There was complete loss of power and sensation in the lower limbs, the penis, scrotum, buttocks, and body up to the level of iliac crests, except over the center of the abdomen (where sensation was good four inches below the umbilicus) and over the spinal column in a space two inches broad, extending about two inches down on the sacrum. The skin of the legs and feet was smooth and shiny, and that of the thighs in good condition, the whole of the limbs being warm. There was some edema. The toes were kept in the position of flexion; the ankle-joints were immovable, but the knees could be passively bent. The knee-jerk on both sides was much exaggerated. The clonus was marked. The scrotal reflex was obtainable from the abdomen. The skin was abraded over the metatarso-phalangeal joints of both great toes. There was a bedsore over the sacrum a little to the left of the median line, a scar of an old sore on the right side, also scars of incisions of former operations in the lumbar region. Some spinal deformity was seen just above the cicatrix of the previous operations.

The patient's condition showed very little change while I kept him under observation for a few weeks. The bladder was irrigated daily with boric acid solution, and the condition of the urine became better. The bedsores looked better, as the sloughs had been thrown off and granulations were present.

On November 7, 1893, I made an incision over the spinous processes of the vertebræ in the lower dorsal and upper lumbar region. The spinous processes of the eleventh and twelfth dorsal vertebræ and of the first lumbar vertebra were cut off, and the laminæ of the same vertebræ were partially removed. The cord and membranes were exposed. The latter were opened; the lower end of the cord seemed to be healthy, but the cauda equina was displaced and was evidently the seat of an old injury. Some cerebro-spinal fluid escaped. There seemed to be an angular displacement of the cord at the dorso-lumbar junction, which disappeared when the bone was removed. The former operations had evidently been in the region of the second and third lumbar vertebræ and a bony ridge had replaced the laminæ removed; this was cut away. I was willing to operate, because the appearance of the spine seemed to show that the whole area of displaced bone had not been removed. At the operation I found that the prominence of the first lumbar spine was largely, if not wholly due to the previous removal of the spinous processes below. The wound was closed with buried catgut and superficial silk sutures, and dressed with iodoform-collodion and gauze. The patient recovered fairly well from the ether and had an uneventful convalescence.

There seems (January, 1894) to be perhaps a little more mobility of the ankle, tarsal, and metatarsal joints, but otherwise the condition of the patient does not differ from that before the operation. His general health is good.

DORSAL LAMINECTOMY FOR FRACTURE OF THE VERTEBRÆ; NO IMPROVEMENT; DEATH FROM BEDSORES.

A man, aged twenty-two years, came under my care on May 23, 1892, for fracture of the spine. He was engaged in a lumber camp, and, as a heavy tree began to fall, he started to run from it. He was struck and felt as if his feet were caught. He was not unconscious, but was somewhat stunned. He was not actually caught under the tree, and the peculiar sensation which he noticed in his feet was probably due to an instantaneous paralysis. He was paralyzed in both legs and soon had the ordinary involuntary evacuations of urine and feces that occur after such injuries. The accident had occurred one year before the patient came to me for treatment, during which time bedsores had formed in the sacral region and on the hips. Sensation and movement below the navel were lost.

On June 16, 1892, laminectomy was performed at the seat of deformity in the dorsal region. The cord was found to be compressed by portions of bone, which were removed. Some days after the operation it was thought that there was some gain of muscular power, for the patient could slightly move his legs at the hip-joints. This appeared to be due to voluntary contraction of the psoas and iliac muscles. It is probable that he had had the same amount of control before the operation, but that it had not been observed. The wound, which had been closed with catgut introduced for drainage, remained aseptic. The catgut sutures, however, became absorbed before union was completed, and the wound gaped, showing an aseptic partially-organized blood-clot filling the wound. The lips of the wound were then brought together with silkworm-gut and gradually became entirely healed without suppuration. Five weeks after operation the patient died with symptoms of sepsis, which was probably due to the large bedsores which occurred on both hips. No autopsy was made.

DORSO-LUMBAR LAMINECTOMY FOR OLD FRACTURE OF THE SPINE, FOLLOWED BY HEMATURIA; NO IMPROVEMENT IN PARALYTIC SYMPTOMS.

A man, aged thirty-seven years, while driving a team under a lumber track, which was not high enough to permit him to maintain the upright position, stooped forward to go under the obstruction. Even in this position he was too high and was caught by the beams overhead and forcibly bent backward, sustaining an injury to the spinal column in the region of the last dorsal vertebra. He became paraplegic at once, and a physician of the neighborhood made an incision over the point of deformity in the spine, but apparently did not perform any operation upon the bones of the vertebral column. About five months and a half later he was brought to Philadelphia and put under my care. The patient was completely paralyzed as to motion and sensation in the lower part of the trunk and in both legs. There was incontinence of urine and feces.

A few days after admission the patient passed a small urinary calculus. His urine was of a high specific gravity and contained pus, mucus, and phosphates, showing the presence of cystitis.

On April 22, 1893, I made an incision four and a half inches long in the median line, exposing the

spinous processes of the eleventh and twelfth dorsal, and first, second, and third lumbar vertebræ. By means of a chisel and gnawing-forceps I removed the arches and spinous processes of the twelfth dorsal and first and second lumbar vertebræ. In this situation the dura was flattened and contained little if any cord-substance for about an inch and a half. There had apparently been a fracture involving the bodies, as pieces of bone or callus were found in the spinal canal. The dural sheath was opened and the cord found uninjured above and below. I made an attempt to bring the two ends of the damaged medulla together, in order that I might suture the upper and lower portions of the cord with catgut. The amount of cord which had been destroyed from the effects of the traumatism was so great that approximation was impossible. The edges of the wound were brought together across the gap left in the bony canal and a dressing of iodoform and collodion applied. A good deal of shock was shown, and the patient had a chill. Strychnin, digitalis, and nitroglycerin were employed and the patient gradually reacted. The day after the operation the patient had retention of urine, although before the operation there was constant incontinence of urine. By the catheter twelve ounces of bloody urine were withdrawn. This hematuria lasted for several days, and the urine had to be drawn on a number of occasions. Gradually the urine became free from blood and the incontinence returned. Two weeks later the patient was sent home into the country in a pretty weak condition, with a temperature above normal. His desire was so great to go home that I permitted him to leave, even though he was not strong.

Five months after the operation he was still living, but his paraplegic symptoms were unimproved. The operation, therefore, has been of no service, but was satisfactory in that it gave him and his friends the comfort of knowing that everything had been done that was possible in the way of surgical relief. For this they were grateful.

LAMINECTOMY FOR FRACTURE OF THE SPINE OF TEN MONTHS' DURATION; NO IMPROVEMENT; DEATH TWO MONTHS LATER.

Dr. L. W. Steinbach has given me permission to report the following case, which he kindly permitted me to see at the time of operation. In April, 1892, the patient, a man of twenty-five years, was caught by falling coal in a mine, sustaining a fracture in the lower dorsal region, with immediate and complete paralysis of both legs. For two months after the injury there was some blood mixed with the urine, which had to be drawn with a catheter. At the time of the operation he had control of the bladder and also of the rectum. His bowels were, however, constipated. On October 27, 1892, Dr. Steinbach operated, making a six-inch incision over the spinous processes of the lower dorsal and upper lumbar vertebræ. The laminæ and spinous processes of the eleventh and twelfth dorsal and of the first lumbar vertebræ were cut away. Upon reaching the spinal canal it was discovered that from two and a half to three inches of the cord were either destroyed or flattened against the vertebral bodies, forming a mere band within the membranes. The membranes, however, were not opened; for at the time of operation it was supposed that neither cord nor membranes remained in this area. The body of the eleventh dorsal vertebra was an irregular mass, as if fracture had taken place at this spot. The patient lost control of his bladder for a few days after the operation and had to be catheterized. He had three attacks of epistaxis. Some days later he regained control of the bladder. The wound healed promptly, but bedsores began to develop in spite of great attention. His temperature gradually began to rise and he died on December 22d. No improvement was obtained by the operation.

GOLD-FOIL IN THE SHAPE OF A CONICAL CUP INTRODUCED INTO A LACERATED CAVITY OF THE CEREBRUM FOR THE PURPOSE OF PERMANENTLY STOPPING THE OUTFLOW OF CEREBRAL TISSUE AND CLOSING A HOLE IN THE MEMBRANES.

By W. L. ESTES, A.M., M.D.,
of St. Luke's Hospital, South Bethlehem, Pa.

It occasionally happens that the exigencies of "acute surgery" bring one to the adoption of a procedure or device not recommended by the "books," but which may serve to establish new lines of practice by demonstrating an unthought-of tolerance of foreign bodies on the part of the living tissues, or suggesting similar attempts to other surgeons. Fluhrer's case of gunshot wound of the cerebrum, with successful localization of the ball by probing through the whole diameter of the brain, gave a new impetus to cerebral surgery that has led to wonderful results. The following case is therefore related as a unique example, so far as I am aware, of plugging the cerebrum *permanently*, with a most happy immediate result and complete and rapid recovery of the patient.

Cornelius B., a negro, twenty-eight years of age, was brought to the hospital in an unconscious condition on the night of April 4, 1893. The Ambulance Surgeon was told that while the patient, with a companion, was out driving, Cornelius, by what means or agency could not be discovered, was thrown to the ground and kicked by the horse, becoming immediately unconscious. He was forthwith taken in charge by his companion and sent by railroad a distance of some twenty odd miles, and finally was received at the hospital, still unconscious, three or four hours after the injury. No dressing or covering of any sort had been placed over the wound. Examination showed no injury anywhere, not even an apparent bruise, except on the right side of his head, where there was a *punched-out* sort of wound through the scalp and the bone and deep into the cranial cavity. The location of this wound was 6.5 centimeters above the external auditory meatus and 2 centimeters in front of a line perpendicular to the external auditory meatus; it was 5.5 centimeters behind and 3.5 centimeters above the external angle of the frontal bone. The wound in the scalp was round, but a laceration extended backward about 3 centimeters. The surrounding scalp was not lacerated or contused. Hemorrhage had entirely ceased and had not been profuse. The man's general condition was

good. Although he was unconscious, enough reflex remained to cause him to move about when the wound was manipulated. After shaving and carefully cleansing and disinfecting his head, he was chloroformed, the external or scalp wound was enlarged and the bone freely exposed. It was found that the depressed fracture of the bone involved an area of a little less than 2 centimeters, and that all of this bone was driven down, at almost a right angle to the cranium, into the cerebrum; so that there was a sharply-defined rim of bone, with some radiating linear fractures, and about 3 centimeters beneath, from the inner table of the cranium, the comminuted fragments lay imbedded in the cerebrum. Outside of this bone the scalp had also been punched out and the fragment was lost. The opening in the bone was enlarged and by careful manipulation the fragments were lifted out of the cerebrum with a pair of narrow forceps. A few spiculæ were so small and sharp and deeply imbedded that much care was required to locate and remove them. When the fragments were finally removed free hemorrhage took place from the cerebrum, but was checked by plugging the cavity with iodoformized gauze. Something like 15 cubic centimeters of lacerated cerebral tissue were washed away with a gentle stream of warm sterilized saline solution. The dura was lacerated to shreds and it was quite impossible to close the gap in the membrane. I concluded to pack the whole cavity with iodoformized gauze, and, by careful asepsis, endeavor to obtain healing by granulation. Accordingly, a careful dressing, with an outside pressure bandage was applied and the patient put to bed. He stood the operation very well, reacted quickly, and under morphin passed a quiet night. The next day he was quite conscious, answered questions readily, and had no paralysis. There had been considerable oozing and the dressings were saturated with blood. I changed the dressings. In spite of the greatest care there was an escape of more cerebral tissue, and as there was no membrane or scalp to help retain it I saw I should have trouble to prevent the escape of brain-tissue whenever I dressed the wound, and every prospect of a final hernia cerebri. I replugged and redressed the wound as before and concluded to wait a day or two. I recollected, in thinking over the matter, that Weir had recently used gold-foil to prevent adhesions between the dura and cranium and scalp, and had found it non-irritating, and that rapid and permanent healing occurred in his cases. My problem, however, was more complicated. I had to control the oozing of the cerebral tissue into a cavity and prevent its detachment and escape on account of a complete loss of all its envelopes. I concluded to try a sterilized cup made of heavy gold-foil fitted down into the cavity of the cerebrum.

On April 7th, two days after the injury, I again had the patient chloroformed, and getting the dimensions of the hole in the cranium I fashioned a cup from the gold-foil (which had been sterilized by immersion in a 5 per cent. solution of carbolic acid and then washed off in a warm sterilized saline solution, 0.5 per cent. solution of sodium chlorid) into the shape of a hollow cone, with the base just big enough to fit closely to the inner rim of the inner table of the cranial wound and with a depth of about 2 centimeters. The plugs were removed from the cerebral cavity, with again considerable escape of brain-matter, which was washed out by a gentle stream of the warm sterilized saline solution and the cup immediately introduced, apex downward. I fastened it in place by pressing the foil into the indentations and irregularities of the rim of the inner table and packed loosely into the cup some iodoformized gauze. I incised and loosened the scalp on either side of the wound so that I could slide it over and cover in the opening, sutured it, except a small space in the center through which an end of the bit of iodoformized gauze was allowed to project, and dressed it as before.

On April 14th the wound was redressed, the sutures removed and also the packing of gauze from the cavity of the gold cup. The wound was perfectly aseptic, the cup firmly fixed and in place, and there was no bulging and absolutely no escape of brain-matter. A small bit of gauze was again introduced into the cup to give it solidity, and the dressings were reapplied.

On April 27th the wound was again inspected. There had been no suppuration, and the wound was entirely closed except where the bit of gauze projected from the cup. This was removed and the external wound was allowed to come together. In a few days this was entirely and solidly united. The patient was allowed to be up and about. His faculties were all good, locomotion was good, and in short he showed no indication in any way of having lost any function; nor were there any signs of irritation from the cup. I kept him about two weeks, employed most of the time about the wards, doing the work of an orderly, that I might observe him and examine the seat of wound. There was absolutely no indication of any trouble or disturbance. He was discharged quite well May 20th. The wound was firmly united and there was no pulsation perceptible through the opening in the cranium.

THERAPEUTIC NOTES.

THE THERAPEUTIC USES OF THE SALTS OF CESIUM AND RUBIDIUM.

BY THEODORE W. SCHAEFER, M.D,
OF KANSAS CITY, MO.

IN the years 1860 and 1861 Bunsen and Kirchhoff, by means of their memorable four-prism spectroscope (which, by the way, was on exhibition at the recent World's Fair in Chicago), discovered the two alkali-metals, cesium and rubidium, while examining the waters of Duerkheim, Germany. Together with others, they succeeded in finding these alkali-metals in many waters, soils, plants, and in the animal system. Further spectrum observations showed even traces of rubidium and cesium in the blood of man, demonstrating the fact that they are widely diffused in Nature, although in minute quantities.

Lucanus experimented with cesium and rubidium upon the growth of plants and claimed that the latter do not absorb the salts of these metals and that they act inimically upon them, but repeated experiments in recent years have shown the fallacy of his claims. In 1864 Claude Bernard, the celebrated French physiologist, experimented with the salts of rubidium and demonstrated that they are less toxic to the cardiac apparatus than the preparations of potassium.

Cesium is the most electro-positive of the elements. Rubidium, its partner, comes next. Cesium and fluorin should be considered as chemic "ideals," because of their prominent chemic and physical characteristics. Fluorin, as I have elsewhere pointed out, is the most electro-negative member of the elements, whilst cesium is the most electro-positive. The chemic, physical, and physiologic activities of cesium and rubidium rank higher than those of potassium, sodium, or the other members of the alkali-group. The presence of cesium and rubidium in plants and in the animal organism must certainly serve a purpose. Just as fluorin, in its electro-negative functions and chemic affinities, is an inherently associated member of the halogens, so does cesium behave as a member of the alkali-metals in its chemic functions and electro-positive activity. The researches of physiologic chemistry teach that substances having allied properties must have also analogous actions upon the organism, and the difference of their modes of action can be explained on chemic principles.

My uncle, Dr. Edward Wernigk, once assistant of Prof. Bunsen, experimented as early as 1876 with cesium and rubidium upon his body. He again repeated these experiments on his own person in 1880, using cesium bitartrate. He believed that cesium and its salts acted favorably upon his heart, as he was suffering from a cardiac neurosis. It also acted favorably upon the generative organs. He assured me that the salts of rubidium and cesium possess the same therapeutic effects as the other alkali-salts. In experimenting upon his person he always took the cesium salts in smaller quantities than when he was taking the other alkali-salts internally. Thirteen years ago cesium salts were very expensive chemicals to experiment with, and as his deductions were mostly speculative he was not prepared to publish his results in scientific journals. I have an unpublished manuscript, written in 1881, in which I have noted the following in regard to cesium and rubidium:

"Since cesium appears to possess the most electro-positive character of the elements, one would rationally suppose that it might play an important function in the animal and vegetable kingdoms. So is it the case with rubidium, the next electro-positive element in rank. It is not difficult to understand that cesium and rubidium, on account of their very high electro-positive nature, probably perform the functional activities of the alkalies in a higher degree. Cesium is reputed to operate toxically upon the nerves of the heart, and the same is stated of rubidium. It is a great question if this be really true. It is more reasonable to suppose that the elements cesium and rubidium, in combination with the halogens, will perform their chemic and physical functions much more conspicuously in the system than the lower electro-positive members of the series."

Dr. Wernigk always used cesium bitartrate in small doses, beginning with ¼ of a grain and increasing to 5 grains three times daily. I have used the bromid and bitartrate of rubidium when experimenting on myself in doses of from 3 to 5 grains three times daily. I used rubidium bromid to alleviate nervous palpitation of the heart. I would have used cesium bromid, but was prevented on account of the high price of the salts of cesium.

As soon as the exorbitant market price of the salts of cesium and rubidium is reduced, there is no doubt that they will often be substituted for potassium or sodium salts. Experience will also doubtless teach that they can be given in larger doses.

Cesium is the ideal alkali-metal. It was the first element discovered by means of spectrum analysis. Chemically it is the king of the alkali-metals, being the most electro-positive member of the elements and outstripping them all in electrolytic conductivity. Metaphorically speaking, it stands with rubidium in the same relationship as gold does to silver.

ACETANILID AS A SURGICAL DRESSING.

Surgical Dispensary, German Hospital.

Service of G. A. BODAMER, M.D.

[Reported by Alfred Hand, M.D., Resident Physician]

Following the suggestion of Dr. Francis W. Harrel in The Medical News (vol. lxiii, page 438), acetanilid has been used in the Surgical Dispensary of the German Hospital as a substitute for iodoform. The results obtained have been most excellent. As stated by Dr. Harrell, acetanilid acts especially well when applied to the lacerated wounds of fingers which mechanics receive, and to which dust, oil, and foreign bodies of every description gain easy access. In the large number of cases of this description (many of which come from Baldwin's Locomotive Works), in which acetanilid was employed, not one has suppurated. Thus healing takes place in a short time, and it is often possible, without keeping the men away from work much longer, to save half of a phalanx, when amputation formerly would have been practised.

Acetanilid has also been used in all fresh wounds (except small scalp-wounds, to which pure ichthyol is applied on lint) which have come to the Dispensary in the last two months, and suppuration has occurred in but four of these: 1. An extensive incised wound of the forearm of a fat woman; it was necessary to suture a tendon and to use twenty-three sutures in closing the wound; there was so much tension that the edges of the wound sloughed afterward, although at the second dressing the wound was dry. 2. A deep, lacerated scalp-wound; there was considerable hemorrhage, and as the bleeding-points could not be readily caught, a compress, on which acetanilid had been dusted, was applied; the man came back after five days and a few drops of pus were found in the wound. 3. A deep, incised wound of the leg, with the tibialis anticus muscle severed. The antisepsis was at fault here, as the skin-wound healed, but suppuration appeared in the muscle. 4. A deep, incised wound between the thumb and metacarpus; some grease had been used as a dressing before coming to the hospital; the skin healed readily, but pus formed deep in the wound.

Some of the more important cases which were successful included a scalp-wound nine inches long, extending from the back to the front of the head; three incised wounds of the arm, with severed tendons; all of the amputations of digits, and, in fact, all of the other fresh wounds.

Simple ulcers, such as follow burns of the second degree, healed promptly without pus under acetanilid.

On chancroids acetanilid does well, at least as well as iodoform, and has the advantage, from the patient's standpoint, of being without odor. In some cases it causes pain for a few moments after being dusted on the sore, and in two cases herpetic vesicles followed its use.

Several syphilitic leg-ulcers, with profuse discharge, have dried up and healed rapidly with acetanilid, coupled with anti-syphilitic treatment. Others, however, have shown no improvement.

Dr. Bodamer has used acetanilid in his private practice, applied to mucous patches, having the patient hold the mouth open for several minutes while the powder was applied. The effect has been remarkable, the patches clearing very rapidly. He also used it in a case of ulceration of the rectum in which malignancy was feared, and prompt healing followed. In a bone-case which had persisted for some time, he secured healing by the use of acetanilid while the patient was confined to bed by an attack of influenza. In one sinus-case, the acetanilid was injected in a watery mixture, and after a few hours profuse sweating occurred, and the patient experienced a rather pleasant sensation as of floating in the air.

Acetanilid has also relieved a moist, eczematous condition, attended with the formation of crusts, around the navel of an infant a year and a half old. The condition had persisted since birth.

Acetanilid is insoluble in water, but soluble in alkalies. As its toxic effects have only followed the internal administration of excessively large doses, it is improbable that enough could be absorbed, after being dissolved in the discharges of a wound, to produce unpleasant effects, unless injected in large quantities in sinuses. In this respect iodoform and acetanilid are on a par. As a desiccant, the latter is far superior, the dryness of the wounds in all cases having been remarkable, the acetanilid being found as a thick, dry crust over the wound at the second dressing. As regards expense, acetanilid can be procured at one-tenth the cost of iodoform.

Of course acetanilid must be used much more extensively before its proper place as a surgical dressing can be determined, but from the results thus far obtained it would seem that it is a cheap, odorless, non-irritant dressing, with antiseptic, anesthetic, and strongly desiccant properties.

INSANITY CURED BY QUININ.

By EDWARD ANDERSON, M.D.,
of Rockville, Md.

Disease often manifests itself in mental derangement only, particularly when there is an hereditary predisposition to insanity. Before placing persons in asylums for the insane, we should look into their histories and carefully note every circumstance connected with their lives, both past and present. On the 11th of June, 1893, I was called to see a colored woman, between seventy-five and eighty years of age, who had suddenly become a raving maniac, tearing her bed and clothing, and inflicting injuries upon herself and everyone who came within her reach. This woman's brother was an imbecile, her sister insane, and two of her daughters had become demented and wandered off. There was no rise of temperature and no disease apparent, but thinking there might be pain in the head, I gave the woman fifteen grains of sodium salicylate three times daily, with slight benefit. I also tried my favorite remedy in such cases, hyoscyamin, but it also failed to quiet or produce sleep. I then used sulfonal, with no better success, and was obliged to resort to chloral, of which a dram a day was required to control the woman. After her children worried with her for two weeks, they determined to send her to an asylum. I knew it was very unusual for a person of her age to become mentally deranged, and remembering that before moving to Rockville she had lived on the brow of a hill overhanging a small stream, which overflowed its banks during every hard rain, I thought I would try quinin. After giving her fifteen grains three times daily for a week, her mind was perfectly restored. A relapse occurred on the 4th of September, which was at once relieved by the same remedy. Except for a slight melancholia, that comes on every other day, and which quinin or arsenic will speedily dissipate, she is as well as ever. Had this woman been young she would probably have spent the remainder of her days in an insane asylum. As malaria is almost unknown in this section, I would not ordinarily have thought of giving an anti-periodic.

PROPHYLACTIC AND GERMICIDAL TREATMENT OF DIPHTHERIA.

By C. H. HAMILTON, M.D.,
of Dubuque, Ia.

For simplicity, facility of application, and efficiency in the topical treatment of pharyngeal diphtheria, both as a prophylactic and as a germicide in developed cases, I use the following with much success:

R.—Hydrargyri biniodidi . . . gr. ij.
Sacchari albi . . . . ℥j.
Olei menthæ piperitæ . . . ♏ij.—M.

S.—Place from gr. v to x in powder every hour or two hours on the tongue or inside the lips of the child, without giving water for a few minutes afterward.

Should laryngeal or tracheo-laryngeal symptoms develop, I use, in addition to the foregoing, also with some success, unslaked lime and turpentine as follows: Place a quart of unslaked lime in a vessel of appropriate size, and pour at first upon it half an ounce of turpentine, and then enough boiling water to completely cover the lime, and place this vessel under a cotton sheet, which is thrown over the head of the nurse and infected child. A cloud of vapor will be emitted for ten minutes at each sitting, which can be repeated hourly if required for the paroxysms of difficult breathing.

A spray of hydrogen dioxid, one part to four of water, is also a great favorite with me.

The biniodid does not coagulate albumin, as does the bichlorid, and for this reason may be more efficient. Well triturated with the sugar and peppermint it is quite pleasant, and, given dry, adheres to the throat, so that the germicide is thus brought well in contact with the surface which may be, or is, infected.

A CASE OF QUININ IDIOSYNCRASY.

By JOSEPH L. HANCOCK, M.D.,
OF CHICAGO.

That small doses of quinin sulphate produce in some persons annoying symptoms, is well demonstrated in a recent case in my practice. A gentleman, a florist by occupation, twenty-six years of age, tall, with a dark complexion, and of rather slight build, was suffering from an acute "cold." The mucous membrane of the nasal passage had been discharging serum, and the general unpleasant sensations following this condition were increasing. Under like circumstances he had some time before taken quinin (two grains), but always with the results to be described.

I saw the man on the morning of December 3, 1893. While trying to attend to his business, he was feeling depressed in spirits and was about to return home in order to be quiet. An intense erythema was present, with sensations of burning and itching over the entire body, including the hands and face. These symptoms were intensified by contact with cold air. The skin of the hands and wrists showed little whitish, apparently bloodless, raised spots. The amount of quinin taken had been two grains on the previous evening; followed in a short time after by another dose of the same quantity, so that the total amount taken was four grains. The intense redness of the skin and other coincident symptoms mentioned progressed until about noon next day, dating from the time the last dose had been taken. Then a gradual subsidence took place lasting through half of the next day, leaving the patient without further serious effects.

MEDICAL PROGRESS.

Enteric Fever; Perforation: Peritonitis: Recovery.—Newton (*Chicago Medical Recorder*, vol. v, No. 6, p. 409) has reported the case of a lad, seventeen years old, who came under observation on the third day after having taken to his bed, with diarrhea, tympanites, and pain in the right iliac fossa. The temperature was elevated and rose-spots were present upon the abdomen. Restriction of the diet to milk and beef-tea, and the administration of a mineral acid and pepsin, and bismuth, salol, opium, were followed by amelioration in the symptoms. On the seventh day, however, the temperature again rose, the pulse became accelerated, small and thready, the face pinched, the skin cold and clammy, the tongue dry, and the abdomen tympanitic and extremely sensitive. It was learned that during the previous night, while a movement of the bowels was taking place, sharp, acute pain was felt in the side. Perforation of the bowel was diagnosticated, and celiotomy advised but not acquiesced in. Morphin, strychnin, and whiskey were repeatedly administered, and by the following day the patient had rallied somewhat. He remained in a precarious condition for several days, when he gradually began to gain ground. For the succeeding three weeks the temperature pursued an irregular course and the diarrhea was particularly obstinate. After the lapse of another week indications of the presence of an abscess between the anus and the scrotum appeared, and three ounces of fetid pus were evacuated. Through the opening made a probe could be introduced into the abdominal cavity for a distance of ten inches. The opening was kept patulous by means of gauze, which was removed after the lapse of twelve days, and the external wound was permitted to heal. From a few days after the occurrence of the supposed perforation complaint was made of a particularly sore spot, about three inches in circumference, below and a little to the left of the umbilicus, and over which percussion yielded a dull note. It is believed that the spot indicated the situation of the local peritonitis that existed, and which remained local from the formation of intestinal adhesions as a result of the exudation of plastic lymph. As peculiar features of the case are pointed out the early date of the occurrence of perforation, the situation in which the abscess pointed, the failure of the temperature to decline, and the absence of vomiting.

Ingrowing Hairs.—Guthrie (*Practitioner*, No. 307, vol. lii, p. 19) calls attention to a condition of ingrowing hairs, which presents itself in the form of bluish-white pimples, varying in size from a pin's head to a small pea, situated usually about the chin where the beard grows the thickest. Careful inspection of the unshaved chin and cheeks will show here and there the presence of "giant hairs." These are dark in color, and as thick as hog's bristles. The slightest traction with forceps suffices to painlessly remove them. The thickening is due to the deposit of a dark, soft material, which envelops the hair throughout its extent. This layer can be scraped off, and is soluble in liquor potassæ. The hair itself is also thickened, aad its structure is blurred and indistinct. It is probable that the little bluish-white pimples form by the growing within the hair-follicle of what remains of a broken, thickened, and brittle hair. The condition occurs most commonly on the bearded face, but it is sometimes observed in other situations, as the axilla, the pubes, the periphery of the hairy scalp. Under the latter circumstances the condition is dependent rather on a blockage of the orifice of the hair-follicle than upon disease of the hair itself. Sometimes, instead of a single hair, such a follicle will contain a minute ring-shaped tress, composed of a dozen or more fine hairs. These are particularly common about the under surface of the penis, where they often suppurate and discharge a foul-smelling mixture of pus and decayed sebaceous matter. In treatment giant hairs should be removed by means of forceps, but it is essential that no force be used. When the little nodules have formed, the overlying surface should be sterilized and an incision made with a sharp tenotomy knife. A portion of hair will present, and can easily be extracted.

The Knee-jerk in Diabetes Mellitus.—Among 131 cases of diabetes mellitus Grübl (*Neurolog. Centralbl.; Wiener med. Presse*, No. 2, 1894, p. 66) found the knee-jerks normal in 113, and exaggerated in 5. Three of the latter, however, presented not true diabetes, but merely the glycosuria of neurasthenia, and in them both the presence of sugar in the urine and the state of the reflexes were to be ascribed to the condition of the nervous system. Among the other 115 cases were nine of the severe type of diabetes mellitus. Of these nine the knee-jerks were exaggerated in two, which pre-

sented great weakness and in which the urine contained large amounts of sugar and acetone, but in which, as in the course of treatment, the general condition improved, the excitability diminished, and ultimately the knee-jerks became normal. In four cases of severe diabetes the knee-jerks were abolished, or greatly enfeebled. The knee-jerks were also wanting in nine mild cases, but in two of these posterior spinal sclerosis coexisted, and in a third there was such an excess of adipose tissue as to interfere mechanically with the elicitation of the phenomenon. The knee-jerks were thus lost in ten cases among 131—7.6 per cent. It was further found that the knee-jerks may be preserved in the most severe cases, even in the presence of coma, while they may be absent in mild cases in which the sugar can be made to disappear by appropriate diet. It thus appears that symptomatically the knee-jerks have little or no significance, either diagnostically or prognostically.

The Surgical Treatment of Pulmonary Cavities.—From a study of the present aspect of the surgery of the lungs, Dandridge (*Annals of Surgery*, vol. xix, No. 2, p. 129) concludes that a certain number of pulmonary cavities can be successfully dealt with by incision and drainage. Tuberculous cavities in the lower portion of the lungs, if single and superficial, and if the general condition of the patient permits, should always be opened. Cavities at the apex should only be opened when there is free and persistent fetid expectoration that has resisted treatment, and the remainder of the lung is not involved. Abscess, gangrene, and hydatid cyst should be opened and drained whenever they can be located. Closure of the pleura should be insured before the evacuation of a cavity is attempted. In cases of pyo-pneumothorax the fistulous track should be explored, and any cavity freely laid open by means of the cautery. Cavities that have been opened are best treated by packing with gauze, preferably impregnated with iodoform. The further careful trial of such agents as iodoform, chlorin-gas, and zinc chlorid is desirable to determine whether or not the tuberculous infiltration may be modified by them. It is also desirable, for the further extension of surgical interference in pulmonary cavities, that the means of locating such cavities and of determining their size and the exact character of the tissue that overlies them should be perfected by further study, and for the accomplishment of this the surgeon must look to the physician.

Stonemason's Neurosis.—Frere (*British Medical Journal*, No. 1726, p. 188) has reported the case of a stonemason, forty-five years old, who was compelled to give up his work on account of tremor of the left hand, with inability "to govern his chisel." The grasp of this hand was found to be distinctly enfeebled. The hand was steady in most positions, but as soon as an attempt was made to grasp the chisel, as if at work, there was set up an incontrollable shaking of the hand. There was no wasting and no painful points. General and special sensibility was preserved, and ophthalmoscopic examination revealed no abnormality. The man complained that when at work the chisel "would dance in his hand." Cramp was noted on only three occasions, each time confined to the little figer, probably because at times the chisel was grasped with the little and ring fingers only. These attacks were of brief duration. Pain, progressive in character, had appeared as follows: in the carpal joint of the thumb, which felt "as if it were broken;" between the metacarpo-phalangeal joints of the first and second fingers; at about the center of the forearm, on the radial aspect; at the center of the upper portion of the forearm, on the anterior aspect; at the shoulder along the tendon of the biceps. The pain in the forearm was at times so intense as to prevent grasping with the thumb or the first and second fingers; at such times these digits would be extended and the chisel grasped with the little and ring fingers. Marked improvement followed rest, massage, and small doses of arsenic.

A Pen and Holder Swallowed.—Plant (*Archives of Pediatrics*, vol. xi, No. 2, p. 141) has reported the case of a fifteen-year-old boy, of limited intelligence, who, after complaining for some days of pain in moving about and in sitting down, told his mother that a week before he had swallowed a pen and holder. A diet of mush and milk, together with castor-oil, was ordered, but proving of no avail, celiotomy was undertaken. The instrument was found and removed without difficulty. It was an ordinary wooden holder, stained red, about six inches long, and had a steel pen attached which pointed downward. It had been carried in the stomach and intestines for about ten days. The boy made a good and uneventful recovery.

THERAPEUTIC NOTES.

The Treatment of Empyema in Childhood.—At a recent meeting of the Medical Society of Hamburg, Schütz (*Therapeutische Monatshefte*, J. 8, H. 2, p. 76) related that of eighteen cases of empyema in children treated by resection of one or more ribs, recovery ensued in all but two, and these were in children under one year of age. The prognosis of operation at this period of life is not favorable, but siphonage is not applicable. The drainage-tube, of considerable size, was permitted to remain, on an average, twenty-four days; the wound had healed in the course of an average period of forty-two days. Operation was undertaken as soon as the diagnosis was made, as the mortality of expectant treatment had been 80 per cent. Left-sided empyemata are particularly dangerous on account of the liability to the development of pericarditis. The resection was made as near as possible to the vertebral column. After the section of rib has been removed the pleural cavity was irrigated with a warm solution of boric acid, intended for the removal of the purulent contents rather than for disinfection. More active disinfectants, such as carbolic acid, are to be avoided on account of the risk of intoxication. Siphonage is not practically applicable in the case of young children on account of the liability of the tube to slip out of place. The operation was invariably well borne.

For Recent Ringworm.—

R.—Thymol. . . . . ℥ss.
Chloroformi . . . . . ℥ij.
Olei olivæ . . . . ad f℥j.—M.
Ft. applicatio.
S.—Apply topically night and morning.

Practitioner, No. 308.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 10, 1894.

THE PRESENT STATUS OF OUR KNOWLEDGE OF BACTERIOLOGY.

THE philosophizing bacteriologist must realize that, in its present development, his science is in an unsatisfactory condition. This view was well expressed in a recent conversation, by a biologist who has devoted much attention to bacteriology, when he compared the bacteriology of to-day with biology before the promulgation of the law of variation. Then the zoölogist confined his study to "typical" animals, ignoring the varieties. So, also, we now speak of "typical" bacteria, of "typical" cultures, of "typical" effects, and we tend to remain in ignorance of the varieties, simply because, in our present knowledge, we have no underlying law which can account for the variations and make them interesting. A few examples will illustrate this point; although, in point of fact, scarcely a page of bacteriology fails to furnish ground for this criticism.

The working bacteriologist meets with curious phenomena almost every day of his practice. Something inexplicable happens to an apparently familiar culture, and it takes on new properties. The morphology of a given bacterium seems to be of an established constancy, until suddenly, and for some unknown reason, it takes on a strange form. One day a certain species of bacilli will show those striking irregularities of morphology known as "involution-forms"; on another day they will appear plump and regular. Certain of these conditions we look upon as typical; the rest, as mere variations.

For lack of a better basis of classification, the pathologist is accustomed to divide bacteria into two classes, pathogenic and non-pathogenic. This division was, to within a very short time, considered quite adequate for practical purposes. In the light of the latest investigations, however, we are forced to conclude that even the pathogenesis of a given bacterium is extremely variable. We are shocked to behold microbes, hitherto considered absolutely harmless, suddenly assume active pathogenic properties. The diphtheria-bacillus is said to exist in two varieties, a pathogenic and a non-pathogenic form. The testimony of competent bacteriologists is to the effect that these two varieties of the diphtheria-bacillus cannot be differentiated by their morphologic and cultural peculiarities,[1] and that the distinction can only be absolutely made by inoculation of susceptible animals. The pathogenic variety of the diphtheria-bacillus is found only in the membrane of true diphtheria; but the non-pathogenic variety is found in various benign throat affections, and in the *throats of apparently healthy individuals*. Here, then, variation plays an all-important and very suggestive rôle.

Under the name *Streptococcus pyogenes*, we find at least two distinct varieties of pyogenic cocci, which are indistinguishable in culture and in microscopic preparations. Inoculated upon the skin of man, one variety of this organism produces only a circumscribed and fleeting reaction; the other produces a widespread erysipelatous inflammation. As an instance of an indifferently pathogenic microbe becoming highly septic, we may cite the rapidly-accumulating evidence against the *Bacillus coli communis*. Not only is this bacillus frequently found as the sole inhabitant of various peritoneal exudates, but it is also found in pure culture in several other inflammatory affections, in which it must surely have gained access from without the body. From the observations of MOORE (U. S. Department of Agri-

[1] Escherich (Berliner klinische Wochenschrift, 1893, Nos. 21–23), in an exhaustive study of this subject, endeavors to furnish some specific differential culture-tests for the true and pseudo-diphtheria-bacilli. The delicacy of these reactions, however, only serves to illustrate the difficulties which beset this work, and to indicate the necessity of much further study.

culture, Bureau of Animal Industry, Bulletin No. 3, 1893, p. 45), we learn that cultures of *Bacillus fluorescens liquefaciens* suddenly took on septic properties, and that a rabbit inoculated with 0.10 c.c. of a bouillon-culture died in seven days. *After three weeks, the cultures lost their pathogenic qualities.* This bacillus has been cultivated in the laboratories of many bacteriologists through many generations, and this is the first suspicion which has ever been cast upon its constantly recognized benign character.

Considering the apparent simplicity of structure of these minute organisms the absence of a well-formulated theory to interpret the wide variation in their morphology and physiology is extremely perplexing. The controversy waging upon the identity of the *Bacillus coli communis* and the *Bacillus typhi abdominalis* illustrates this point. Certain structural features, as the tendency to form long threads, and the characteristic flagella, are said to distinguish the typhoid-bacillus from the colon-bacillus. But colon-bacilli are sometimes observed growing into threads, under certain conditions; and MOORE (*Wilder Quarter Century Book*, 1893) has shown that, as regards the flagella, it is impossible to distinguish *B. choleræ suis*, *B. coli communis*, and *B. typhi abdominalis*. Then as regards their physiology, typhoid-bacilli are said to be actively motile, while the colon-bacilli possess but slight motility. But in old cultures of each of these organisms, no difference can be detected in the motility of individual bacilli. The property of inducing fermentation in glucose-solutions, with the production of gas, and of producing indol in beef-peptone solution, has been regarded as distinctively characteristic of *B. coli communis*. A French observer, however, comes forward and claims that, by growing *B. typhi abdominalis* under new conditions, it may also be induced to give rise to fermentation and to the indol-reaction. Moreover, between what we may regard as "typical" colon-bacilli on the one hand, and "typical" typhoid-bacilli on the other, there is a whole series of intestinal bacilli, known under various names, and described by various bacteriologists, which represents a very perfect gradation from the one typical microbe to the other. Are these intermediate varieties to be regarded as transition forms? And is *B. typhi abdominalis* to be regarded as nothing more than a modified variety of the ever-present *B. coli communis?*

Problems such as these haunt the bacteriologist's daily work, and convince him that he has but mastered the alphabet of his wonderful science. While we are ready, then, to give to bacteriology its full share of credit, we must not forget that its very youth largely explains its manifest shortcomings.

THE TREATMENT OF LATERAL CURVATURE OF THE SPINE.

FROM time to time there are, in medicine, as in the allied sciences, periods of inactivity, during which the profession, surfeited with the pleasure of some new discovery, languidly rests upon its laurels before entering upon another conquest. The present appears to be such a season in the history of orthopedic surgery. The impetus given by subcutaneous tenotomy, antiseptic osteotomy, forcible manual and mechanical restoration, resulted in a certainty of cure in club-foot never before attained. Since these innovations no decided advance in any department of orthopedic surgery has been made; but generous discussion upon the etiology, pathology, and treatment of lateral curvature of the spine has resulted in greater uniformity of view, and manifests a tendency to lead to some definite conclusion in regard to the prevention and correction of this unsightly deformity.

The obstacles that have hitherto prevented the earlier solution of these problems have been the want of literary research, anatomic investigation, the application of mechanical therapy, and the desire of each orthopedist to credit himself with the application of a new principle or the invention of a new apparatus. This status of affairs is well illustrated in a recent contribution by BIDDER (*Deutsche medicinische Wochenschrift*, 1893, No. 52, p. 1378), who describes as "meine elastische Pelotten-bandage" what is, in principle, BARWELL'S elastic apparatus.

The difficulty with the modern orthopedist in regard to scoliosis has been in receiving so much material at second-hand, without sufficient research. In no department are original articles so valuable as in orthopedic surgery, as apparatus must be described as well as illustrated; abridged descriptions are often worthless, and reproduced illustrations lose much in the reproduction. The earlier writers, as COPELAND (1815), SHELDRAKE (1816), BAMFIELD (1824), SHAW (1827), COULSON (1839), TAMPLIN (1846), and LONSDALE (1857), were very thorough in their clinical observation, and recorded much that if

carefully studied by the modern orthopedist would enable him to avoid absurd repetition. Many of the methods of treatment and the roughly-constructed apparatus were the result of a false pathology. The abandonment of tenotomy in lateral curvature by that prince of tenotomists, JULES GUERIN, and also by his contemporary, PROF. LEWIS H. SAYRE, was an advance in the right direction. The removal of the cumbersome and injurious supports constructed after, but not improvements upon, the pattern of SHAW, was also an advance, and to-day the modern orthopedist has reached a position but slightly in advance of LONSDALE in the pathology and treatment of scoliosis. Ordinary habitual scoliosis may best be considered in three classes, according as the degree of the affection is mild, moderate, or severe.

These three degrees likewise indicate the prognosis, for a positive cure may be promised in the mild cases, great improvement and possible cure in the moderate cases, and little improvement and but slight amelioration in the severe cases.

The treatment of the mild forms is now a completed chapter, the modern innovations and modifications of the gymnastic methods being but fanciful changes of nomenclature and efforts at self-advertisement.

The prosthetic improvement of the incurable cases may be left to the judgment of the surgeon, the skill of the mantua-maker, or the fancy of the afflicted individual.

The treatment of the medium cases is the "bone of contention" for modern orthopedic discussion and experimentation. It is in these cases that the question of the treatment by means of pressure-correction comes up for consideration. In these, mechanical appliances are proposed and employed to forcibly stretch the contracted curves, the force being gradually increased and repeatedly applied. Two forms of correcting appliances have been employed: (1) those placing the trunk in correcting attitudes, and (2) those designed to exert direct correcting pressure, and BEELY, LORENZ, HOFFA, REDARD, and BRADFORD and BRACKETT have shown that a great amount of force can be employed without injury, and that practical results can be obtained in this manner.

These methods are yet upon trial, but they indicate an advance which promises to render possible the cure of all of the moderate cases and the improvement of some of the severer forms. They are, however, applicable only to the neglected forms of hospital cases, for, if properly treated, scoliosis in private practice but seldom reaches these severer forms.

The subject of forcible correction of scoliosis should be looked upon as modern surgeons look upon resections of the major articulations, especially the hip-joint—as a *dernier ressort*.

MR. HOLMES summed up his remarks upon the excision of the hip "by the statement that it ought to be very rarely indeed required, if the diease were treated properly at its commencement." The same statement applies with greater emphasis to the forcible mechanical correction of scoliosis, and we may add that it ought *never* to be required if the disease be properly treated at its commencement.

REFORMS IN THE TREATMENT OF THE INSANE.

THOUGH great advances have been made in our knowledge of the etiology, nature, and recognition of the various forms of insanity, a corresponding improvement has not been effected in our modes of management and methods of treatment of the insane. The causes of this disparity may be traced largely to the older, false conceptions of insanity and the enactment of complicated laws providing for the incarceration of its unfortunate victims.

In a paper read at the International Congress of Charities, Correction, and Philanthropy (Section IV, on the Commitment, Detention, Care, and Treatment of the Insane) held in Chicago in June last, DR. STEPHEN SMITH (*American Journal of Insanity*, vol. l, No. 3, p. 325), who for six years was Commissioner on Lunacy for the State of New York, made an eloquent and philosophic plea for a revision of existing laws appertaining to the disposition of the insane. He pointed out that these laws are but elaborations of ancient laws, unmodified by the advances that have been made in knowledge concerning the nature and treatment of insanity.

The insane person is almost universally treated as if he were criminal, as one dangerous to the welfare of society, and not, as he properly should be, as a sick person.

In many States the physician plays but a subordinate part in the determination of the existence or non-existence of insanity and in the disposition of the case, while in some the entire matter is decided by persons wholly without medical training. As a natural outcome of such a course of procedure the

treatment is conducted upon an expectant basis rather than from an aggressive standpoint. Too often the institution for the care of the insane is looked upon as an asylum rather than as a hospital. Modern investigation, however, has shown that insanity is but a manifestation of cerebral disease, and that its victims are sick, just as the victims of disease of the lungs or other organs or structures are sick, and that the one, like the other, requires medical care and observation in order to restoration to health; or, if incurable, that life may be made as comfortable and as useful as possible.

The question of depriving an insane person of liberty should be decided upon the same lines that are pursued in the determination of the isolation of a case of contagious disease, *i. e.*, the danger to the individual and to the community, and the ability or the inability of the friends of the patient to make the necessary provision. As cases of insanity usually first come under the observation and care of the family physician, he should be authorized to issue certificates of insanity, to continue in force for a brief and limited period of time. In case it be deemed necessary for the welfare and safety of the patient and others that he be placed under the care and treatment of a hospital for the insane, this certificate should be transmitted to the appropriate hospital-official, whose duty it should be to detail a medical officer to make a personal examination and such inquiry as may seem necessary to confirm or correct the opinion of the first examiner. In the discretion of this officer the patient may be removed to a hospital, where within twenty-four hours another examination is made and the previous findings verified or revised. The certificate thus properly approved and indorsed should, within a short time, be forwarded to a Committee on Lunacy of the State Board of Charities.

In order to remove the impression that hospitals for the insane are custodial rather than curative in aim, radical changes in both the construction and the management of such institutions will be necessary. More, of course, can be accomplished in this direction in the newer States than in the older, but even in the latter existing conditions can be favorably modified, and in the erection of new buildings the reforms contemplated can be made effective.

It is desirable that patients be classified (1) according to sex; (2) according to the nature of their disease; (3) according to the stage of their disease; and that there should be (4) a department for convalescents and (5) one for incurables. Where practicable a cottage-plan of organization would perhaps be the best, provision being made for accessory features, such as a school, a place of amusement, opportunities for engaging in industrial and agricultural pursuits. The superintendent of such an institution would have to be a throughly equipped medical man, specially qualified by education and experience. The care and treatment of the cases should be placed in the hands of attending physicians, who should have had at least one year's experience in the hospital treatment of the insane, and of whom there should be at least one for every hundred curable patients. The immediate care of the patients should be intrusted to first and second assistant physicians, who should be selected from recent graduates and receive adequate compensation, and of whom also there should be one to every hundred acute cases. The following departments would seem essential: a reception ward or hospital; a department for acute cases; a department for convalescents; a department for incurables.

The propositions embodied in the several recommendations of DR. SMITH seem so thoroughly rational and so humane, and the results to be reached of such great importance, that we earnestly urge their early acceptance and enforcement.

EDITORIAL COMMENTS.

The Seminal Fluid of Tuberculous Patients.—Numerous observations have been made upon the seminal fluid of persons suffering with some form of tuberculosis, with results that have been rather contradictory. A recent study by SPANO (*Gazetta degli Ospitali*, November 11, 1893, p. 1418; *Revue de la Tuberculose*, 1893, No. 4, p. 322) would seem to demonstrate conclusively the infectiveness of seminal fluid from cases of pulmonary tuberculosis, even when the genito-urinary tract is uninvolved. The investigation included eight cases—six of pulmonary tuberculosis and two of tuberculous arthritis. In the former and in one of the latter the spermatic fluid was obtained from the seminal vesicles after death, under appropriate antiseptic precautions. In the remaining one the fluid was obtained in the course of an ordinary emission. To exclude the possibility of the existence of a beginning tuberculosis of the genito-urinary tract that might escape macroscopic observation, histologic examinations were made in all of the fatal cases. In all of the cases cover-glass preparations were made and stained by approved methods. In three, tubercle-bacilli were readily detected; in five, not at all; in one, bacilli were found only after the fluid had been treated with caustic soda and boiled, the supernatant fluid being decanted. Intra-peritoneal injection

of a portion of the fluid was practised in seven cases, with success in five. Vaginal inoculation was practised in four instances, with success in two. Cultivation-experiments were undertaken in six instances, with success in three. In neither of the two cases of tuberculous arthritis was the seminal fluid infective. While the number of observations is perhaps too small to warrant ultimate conclusions, the results are, to say the least, extremely suggestive.

The Morality and the English are Much Alike.—The following letter was recently received by a general physician of Philadelphia from an optician:

Respected Sir: Mr. —— —— —— is a practical optician of 34 years standing and 16 years with —— —— —— and their foreman; would like to make arrangements with you to send as many of your patients as you can, and in order to make it pay you I will allow you 25 per cent of the gross receipts of your patients; in order to make this arrangement I will offer you a few suggestions. When you have a patient before you who complains of headache or any trouble with the eyes or glasses, or if you observe that they cannot see as well as they should with the glasses they are using, or if they do not wear glasses, recommend them to me at once to see if I cannot give them something better. Give them my introduction card and tell them by showing this I will as a personal favor to you make an examination of their eyes without any charge. You will be surprised how many patients you will send and the amount of commission that will be to your order at the end of a month, besides having your patients come back to you for other treatment. If you send your patients to a prescribing oculist you will probably never see them again as they would prefer the oculist to treat them for everything while I only examine the eyes for glasses.

—— —— —— —— will wait on you to-morrow during your office hours. Your perusal, patronage and co-operation respectfully solicited.

—— —— ——

SELECTION.

THE TERMS "INFECTIOUS" AND "CONTAGIOUS."

The word "infection" has been and is still used in various senses.

1. By some writers it is used, in distinction from contagion, to indicate the transmission of disease without personal contact, as through the air and infected things, not persons. This usage, once common in medical writings and still popular, is dying out among physicians and is no longer supported by the best medical authorities.

2. According to another usage, infection refers primarily to a diseased condition characterized by certain symptoms and lesions, and only secondarily or not at all to the nature and mode of transmission of the morbific agents causing the disease. The etymology of the word—from *inficere*, to taint, to spoil—seems to justify this meaning, but there enters also into the etymological sense the conception of something introduced from without. The morbific agents capable of producing infection in this sense are heterogeneous, and not easily classified, including many, but not all, pathogenic bacteria; some, but not all, pathogenic fungi; some, but not all, pathogenic protozoa; a few parasitic worms, notably trichinæ; some, but not all, toxic bacterial products; some poisons produced by other vegetable cells, as abrin and ricin; and some poisons produced by animal cells, as snake-venom. These poisons, produced by vegetable and animal cells, belong mainly to those called ptomains, leukomains, and toxic proteids. It will be observed that this second definition of infection is essentially clinical. This use is not common, and is not to be recommended.

3. Modern investigations have shown that the most common and typical infectious diseases, according to any signification of the term infectious, are caused by the invasion and multiplication of pathogenic microorganisms; and it is now customary, at least among bacteriologists, hygienists, and pathologists, to limit the term infection to the morbid condition caused by the entrance and growth within the body of pathogenic microörganisms, and to the act or process by which disease is thus caused. Infection in this sense refers to the nature of the morbific agents causing disease, and implies nothing as to the mode of transmission of these agents. The pathogenic microörganisms which we now know to be concerned in causing infections belong to the classes bacteria, fungi, and protozoa, but we know nothing about the specific agents of infection in many, and these among the most typical, infectious diseases, such as exanthematous fevers. Infectious diseases, as thus defined, form a tolerably definite and well-recognized group of affections.[1] An infectious disease may be localized or general.

According to this third definition, which is the one followed in the present article, infections are distinguished from intoxications. Poisoning with bacterial products plays the chief rôle in producing the phenomena of an infectious disease, and it is impossible to draw any sharp dividing line between intoxication and infection, but it is believed to conduce to precision and clearness to regard as agents of infection only such as are capable of reproduction—that is, such as are living organisms—and not to include among these agents chemical poisons, whether produced by bacteria or other vegetable cells or by animal cells.[2]

[1] The not very happy term, at least in its English dress, "invasive diseases" (Invasionskrankheiten), has been employed to designate other parasitic diseases, particularly those caused by entozoa. One is certainly reluctant to exclude trichinosis from the list of infectious diseases, as well as to admit to the list most of the diseases produced in human beings by fungi, such as thrush and the dermatomycoses. This reluctance is due to the fact that we cannot well abandon the conception that infection implies a permeation of the body with microörganisms or their products, such as we generally observe in bacterial diseases. If, however, we take a broad view of the relation of fungi to diseases of some of the lower animals, and especially to plant-diseases, we can hardly fail to include pathogenic fungi among infectious organisms.

[2] The difficulties which arise if we include, as is sometimes done, among infectious diseases simple intoxication with bacterial products without the entrance and multiplication of the causative bacteria within the body, are numerous. The bacteria concerned in the not unimportant group of affections caused by the reception of ptomains and some other bacterial products formed outside of the body, as in poisoning from decomposing meat, fish, milk, etc., are mostly strict saprophytes, incapable of parasitic growth in the body of the infected animal. It is only cer-

The old terms contagion, miasm, and miasmatic contagion no longer answer the purpose of modern medicine, but it is necessary to give the student some idea of the meaning attached to them.

A contagious disease is one capable of communication from one individual to another by means of direct or mediate contact. The introduction of the expression mediate contact in this definition is necessary, but it greatly lessens its precision. In ordinary use the epithet contagious is applied only to those diseases which are readily communicable from individual to individual, so that a person affected with the disease is a source of danger to those in proximity to him. When the infectious agent is eliminated from the diseased body only in such a way, as by the feces, that it is not likely to be directly received by a second individual, but takes a roundabout way, as through the ground and water, to reach another individual, then the disease is not usually called contagious, although under certain circumstances it may be so. Typhoid fever and Asiatic cholera are examples of such diseases.

It is evident that the term infectious diseases is a more comprehensive one than contagious diseases, and is not strictly comparable with the latter, as the former refers to the nature of the agents causing the disease, and the latter to the manner of transmission of these agents from individual to individual. It is also clear that the limits of what shall be called contagion are indefinite and arbitrary. It is not uncommon to speak of any infectious agent as a contagium. Whether or not an infectious disease is contagious in the ordinary sense depends upon the nature of the infectious agent, and especially upon the manner of its elimination from and reception by the body.

Most, but not all, contagious diseases are infectious. Scabies is a contagious disease, but it is not infectious.

A miasmatic disease is one caused by an ectogenous infectious agent, neither directly nor indirectly derived from another case of the same disease. The type of a miasmatic disease in the sense defined is malaria or the malarial diseases. The cause of malaria is a protozoön, which multiplies within the body, but, so far as we know, is never eliminated from the body in a living state capable of infecting another individual or the locality. The term miasm is sometimes used in a loose sense to designate infectious agents coming from the water or the ground, especially when believed to be conveyed by the air, or even to designate noxious gaseous emanations and undefined effluvia from the ground.

The expression miasmatic-contagious diseases was introduced in order to explain the often complicated, and even yet not thoroughly understood, modes of spread of Asiatic cholera and typhoid fever, and especially to this group was attached a variety of hypotheses, now for the most part overthrown, and which it is not necessary here to mention. In this group of so-called miasmatic-contagious diseases the infectious agent is eliminated from the diseased body in the living state, but in such a way that it is not likely to be directly received by a second individual; and to produce a second infection it must take ordinarily a path, often circuitous and tortuous, and not always easily traced, through various external media. This transit may be influenced, in ways which we now only imperfectly understand, by different meteorological and telluric agencies.—Dr. Wm. H. Welch, in *Pepper's Text-book of the Theory and Practice of Medicine*, vol. ii.

tain poisonous products of bacteria which anyone would think of considering as infectious agents, and it would not be easy to define which toxic product should be admitted to the group and which excluded. If we admit as infectious agents toxic products of the bacterial cell, there is no reason why we should exclude similar chemical substances, particularly the toxic albumoses, produced by other vegetable cells and by certain animal cells. Poisoning by snake-venom is clinically a typical infection, and is so regarded by Virchow and others, who adopt a clinical rather than an etiological meaning of the word "infection."

If there were any chance, as there is not, of the word "infection" disappearing from medical nomenclature or from popular use, or if there were any good substitute for this word, it would probably not be worth while to try to adapt this old term to our modern conceptions, based upon a more exact knowledge of the causation of disease, and it might be left to the vague and loose meaning which has always attached to it in the minds of the people.

CORRESPONDENCE.

LONDON LETTER.

(From our Special Correspondent.)

The Pulse in Diabetes and the Treatment of Diabetes—Trephining for Hemorrhage in Brain-compression after Injury—Subphrenic Pyo-pneumothorax—A Test of Dr. Brown-Séquard's Orchitic Fluid—A Peculiar Form of Paralytic Dementia.

Dr. Saundby draws attention to the prognostic significance of the pulse in diabetes. The presence of excess of sugar in the blood is productive of sufficient obstruction to the circulation to cause an increase in the intra-arterial tension so long as the heart acts with normal vigor, but as the disease progresses nutritional changes are apt to affect the muscular structure of the heart, and with their development the pulse becomes feeble and easily compressible, thereby becoming an index of the wasting heart and a prognostic sign of most unfavorable augury. Speaking empirically, loss of knee-jerks is also found to be a sign of bad omen.

In regard to treatment, Dr. Saundby insists that the first thing to do is to find out the influence of a complete non-starchy, non-saccharine anti-diabetic diet, one, that is to say, consisting of meat, eggs, fish, jelly, almond biscuits, and cakes, tea or coffee, and mineral water. This is difficult to put up with for long, but it can be borne for a few days, and a few days will tell how far the glycosuria is dependent on the carbohydrates taken as food, and how far, therefore, it is worth while pushing dietetic treatment; for it is most undesirable to keep diabetics who are losing flesh and strength on too strict a diet, and Dr. Saundby goes so far as to say that every diabetic should be allowed as much carbohydrates as he is able to *assimilate*, estimating this by the amount of urine and sugar and the body-weight. A pint of milk and two or three large potatoes daily may often be added to the diet with very little increase of the glycosuria and with great benefit to the patient. Green vegetables, sea-kale, celery, salad, cream, cream-cheese, cheese, isinglass, blanc-mange, and

Irish and Iceland moss are aids to diabetic cookery. Irish moss is a very useful article, supplying a basis for puddings of which a great deal can be made by a good cook. Carbohydrates can also be given to diabetics in the form of levulose, or left-handed sugar, to the extent of one and one-half ounces daily, divided into three doses. It cannot be given in sufficient quantity to constitute an important nutriment, but it is most grateful to many patients, and it is one way of giving the quantum of carbohydrate, which, after all, is essential to even a diabetic's welfare. At least once a week a note should be taken of the body-weight, the total daily urine, and the total daily sugar, for if carbohydrates are given their effects must be carefully watched. Tea or coffee sweetened with saccharin or levulose may be drunk, or Bordeaux claret, or whiskey, or unsweetened gin, not exceeding four ounces a day and well diluted, or even in some cases a little bitter ale.

Two cases recorded by Mr. Littlewood, of Leeds, show the importance of considering carefully the desirability of seeking for internal hemorrhage whenever an injury in the region of the middle meningeal artery is followed by symptoms of compression. In the one case he trephined in the Rolandic region and found large clots, with free hemorrhage going on. The trephine used was a large one, but more bone was rapidly removed by Hoffman's forceps in the direction of the anterior inferior angle of the parietal bone, and on turning out the clot a torn vessel in the dura mater was exposed and was with some difficulty secured. For three days the patient improved and became able to answer questions, but he died five days after the operation. At the *post-mortem* an extensive fracture was found, together with suppurative meningitis. In another case, which died four and a half hours after the injury and in which nothing was done, the *post-mortem* showed a depressed fracture and a large clot (a teacupful) between the bone and the dura mater. No tearing or laceration of the brain could be discovered and the other organs appeared healthy. A laceration of the trunk of the middle meningeal artery was found very near the foramen spinosum. It is clear that in all *post-mortem* examinations of cases of this nature, care should be taken to discover and record the position of the bleeding-point as a guide to surgeons who may operate in similar accidents. It is also clear, however, that in any operative procedure for the control of meningeal hemorrhage the surgeon must be prepared to go far down, even to the foramen spinosum, and that he must be armed with means, such as a curved needle, for passing a ligature under the artery in this position. The difficulties of such an operation must be very considerable, and if, on exploration, it became clear that the hemorrhage came from low down, it possibly would be the simpler and safer plan to proceed at once to the ligature of the external carotid.

Dr. Lee Dickinson draws attention to the condition known as subphrenic pyo-pneumothorax, of which he details two cases and tabulates twenty-three others from the *post-mortem* records of St. George's Hospital. The causes of this condition are perforations from various lesions of air-containing viscera; although often well marked, the signs do not extend to the summit of the thorax, where normal phenomena are found to persist; the heart, moreover, is displaced far less than in true pneumothorax. It need hardly be added that these cases are very fatal. The previous existence of dyspeptic symptoms, together with a distribution of the physical signs somewhat different from those in true pneumothorax, should make one suspicious. The physical signs are such as amphoric breathing, metallic tinkling, and bell-note. Early in the history of the case there is often but little to raise the suspicion that the disease has an abdominal origin, except the fact of the onset of the symptoms having been preceded by sharp abdominal pain. The diagnosis is not especially embarrassing, but cases occur in which the signs observable are principally thoracic. It would appear that in most cases, before the end, the diaphragm becomes perforated, and a true pyo-pneumothorax results. When this takes place, the stomach, the duodenum, or other parts of the intestines may be affected, but by far the most frequent perforations are from simple gastric or duodenal ulcers. With the resulting abscess tympanitic resonance projects toward and partly occupies the abdomen at the same time that it produces physical signs within the chest.

A careful test has lately been made of the value of Dr. Brown-Séquard's orchitic fluid at the Hospital for the Paralyzed and Epileptic. Drs. Wood and Whiting, the house-physicians, used it in twenty-three cases of chronic nervous disease, only one of whom showed any improvement in physical condition during the course of treatment, and as this patient was an alcoholic and relapsed again after leaving the hospital, it is open to doubt whether even in his case the injections had any causative influence in producing the improvement. It is interesting, however, to note that notwithstanding this absence of any improvement in the physical condition, nearly all the patients expressed themselves as feeling better after the injection. Perhaps it is even still more interesting to observe that two patients treated with all the same formalities by injection only with distilled water, felt very decidedly better. Two patients stated that they could feel pinching sensations in the paralyzed limbs about three minutes after the injection; both of these patients were the subject of functional disease. The observers contended that they had obtained no results which would justify further trial of this method of treatment.

Mr. Hutchinson describes a peculiar form of paralytic dementia that occurs in connection with inherited syphilis, notwithstanding the comparative rarity of diseases of the nervous system in association with this disease in its hereditary form. This condition of dementia with paralysis appears to occur between the ages of three and six years and is rather aggressive. A child who up to that age may have been of average intellect and quite free from paralysis may in the course of a couple of years be reduced to a condition of the most helpless idiocy. It seems probable that it may be an affection of the cortex, very possibly beginning in the pia, and that the nervous changes are of a degenerative nature; the onset is not marked by any of the more severe head-symptoms, such as pain, convulsions, etc., which usually attend the presence of gummata, but it is not improbable that a transitory stage of congestion may precede the degeneration. Until the attack began the children seemed as intelligent as any, and the physiognomy was not suggestive of syphilis, but gradually the

limbs became weak, the little patients ceased even to try to save themselves from falling, speech became indistinct and was gradually lost, and in the end a condition of apathetic helpless idiocy was reached. The possible connection of this state with congenital syphilis is worth bearing in mind; it seems quite in keeping with other manifestations of that disease that it should show no signs for some years after birth. The keratitis and deafness which not uncommonly arise from inherited taint both of them usually set in at an age approaching adolescence.

NEWS ITEMS.

For the Prevention of Tuberculosis.—After careful consideration of the advisability or not of compelling the registration with the Board of Health of cases of tuberculosis, the Sanitary Committee of this Board has presented an elaborate report, of which the following abstract contains the essential points:

"Consumption is an infective disease, caused by the bacillus tuberculosis. All cases take origin directly or indirectly from other cases. A most common mode of infection is by inhaling dry and pulverized tuberculous expectoration. It is a distinctly preventable disease. If all this be true, and it is based upon the most reliable scientific data, it becomes imperative that all known precautions should be employed to prevent the spread of this disease, and particularly because it is one of the most widespread of maladies.

"During the ten years, 1884–1893, there were 28,289 deaths from consumption in Philadelphia, the mortality from diseases from all causes during the same period being 217,082. The percentage of deaths from consumption to all deaths is thus seen to be 12.52. This is approximately the average percentage of deaths from this disease for the whole country. In order of numbers it stands at the head of the list of deaths from all causes. During the same period the deaths in Philadelphia from diphtheria, membranous croup, scarlet fever, typhoid fever, and smallpox combined were 7.31 per cent. of the deaths from all diseases.

"The question is not whether the most active and continuous effort should be made to prevent the spread of this fatal disorder, but whether the Board of Health should assume this duty in conjunction with the attending physician, and, as a prerequisite in the performance of this duty, require the registration of all cases of this disease. There seem to be valid reasons for believing that the registration of pulmonary tuberculosis would be beneficial."

After referring to the other means of communicating the disease, such as, for example, the use of infected milk and heredity, which are governed by other regulations of the Health Board, the report goes on to say that it would not be wise to antagonize public sentiment, which is not yet educated and aroused to the necessity of official interference, and strike terror into the hearts of the sufferers from the disease by abruptly compelling registration. A middle course is suggested, which would not be offensive, comprising the encouragement of registration as a preliminary to a future requirement, and requiring disinfection on the advice of the attending physician, after the death or removal of the patient. The report continues as follows:

"The weight of medical opinion in this city appears to be against the registration of pulmonary tuberculosis and the assumption by the Board of Health of the duty of active supervision and disinfection, and thus the medical profession indirectly assumes the responsibility of administering the necessary prophylactic measures applicable to this disease. It is, therefore, right and proper and necessary that the profession should realize acutely the weighty obligation which they have assumed, and they should coöperate with the Board of Health in the distribution, in the households where this disease exists, of circulars of information upon the prevention of consumption, and advise the Board of Health whenever disinfection is required. The distribution of official circulars will have the effect of enforcing attention to those sanitary details so apt to be neglected or overlooked, and thus diminish the risk of contagion in the community."

In view of its conclusions the committee offered a series of resolutions, which were adopted. They embrace recommendations that registration be postponed for the present; that circulars containing rules for the prevention of the disease be distributed; that physicians be requested to coöperate with the Board in the distribution of these circulars, and to notify the Board of cases in which disinfection is required; that a medical inspector visit each house in which a death from tuberculosis has occurred, and satisfy himself that the premises have been disinfected, and that all cases of tuberculosis reported to the Health Bureau be recorded as are cases of other contagious diseases.

Accompanying the report was a circular setting forth the various means by which tuberculosis can be communicated, and the methods of preventing its spread.

Pennsylvania Training-school for Feeble-minded Children.—At a recent meeting of the Board of Directors of the Pennsylvania Training-school for Feeble-minded Children, at Elwyn, the following medical and surgical staff was appointed: Neurologists—Drs. S. Weir Mitchell, H. C. Wood, Charles K. Mills, J. Hendrie Lloyd. Physicians—Drs. J. Madison Taylor, D. T. Laine. Surgeons—Drs. W. W. Keen, John B. Deaver. Orthopedic Surgeon—Dr. T. G. Morton. Otologist—Dr. C. S. Turnbull. Ophthalmologist—Dr. S. D. Risley. Laryngologist—Dr. S. Solis-Cohen. Gynecologist—Dr. A. E Broomall. Pathologists—Drs. H. W. Cattell, Joseph Leidy. Dental Surgeon—Dr. T. C. Stellwagen. Chief Resident Physician—Dr. M. W. Barr. Assistants—Drs. Frank White, Louise H. Llewellyn.

Medical Society of the State of Pennsylvania.—In view of the fact that the largest hotel in Gettysburg was burned recently, and will not be rebuilt in time for the coming meeting of the Medical Society of the State of Pennsylvania, to be held May 15th, 16th, 17th and 18th, 1894, it was thought proper, after consultation with the Board of Trustees, to change the place of meeting, and as the Philadelphia County Medical Society extended an invitation to meet in their city, this was accepted.

SPEECH WITHOUT A LARYNX.[1]

BY HARRISON ALLEN, M.D.,
DIRECTOR OF WISTAR INSTITUTE, UNIVERSITY OF PENNSYLVANIA.

I HAVE the honor to report the following facts in the case of Daniel Hickey. This man talks after the removal of the larynx. The operation was performed for epithelioma by Dr. J. Solis-Cohen at the Jefferson College Hospital, April 1, 1892.[2] Dr. Cohen informs me that the parts removed included the entire larynx (excepting the free portion of the epiglottis). The first ring of the trachea was removed with the larynx, and the second was stitched to the skin of the front of the neck.[3]

The patient was mute after the operation for nearly a year, when speech returned. Inspection of the external part of the neck showed a T-shaped scar extending from the tracheal opening to near the position of the hyoid bone. The greater part of this region was occupied by a sac of irregular shape, measuring about 45 mm. in length by 26 mm. in width, whose anterior wall was the integument, and which could be easily pressed back against a resistant surface, which was doubtless that of the cervical vertebræ. The skin, which in part was occupied by scar-tissue, was perforated near the junction of the level of the old transverse and longitudinal incisions by a minute fistulous track. Bubbles of air and a little mucus escaped from this opening. Owing to the prominence of the bellies of the sterno-cleido-mastoidei muscles the sac was in a depression whose lateral boundaries were not fixed. The sac-wall apparently had no muscular power, and was exceedingly flaccid. It will be seen that it moved freely from slight forces exerted within the mouth and pharynx. Its size varied only with the amount of air or fluid it contained. The tracheal opening was red in color, and apt to be coated by scales of inspissated mucus. The position of three rings of the trachea could be made out by the unevenness of the tracheal surface rather than by any contrasted effects of colors. The trachea moved slightly (synchronously with the pulsations of the heart) from left to right.

Examination with a laryngeal mirror, placed as in the position usual for laryngoscopy, showed the base of the tongue and the epiglottis to be normal. The epiglottis was large, broad, and but slightly depressed in the center. It stood erect. A deep, funnel-shaped depression, answering to the interior of the sac, extended from the pharynx downward. No details could be detected within the sac other than a small scar-like structure at the posterior border of the aperture. This appeared to be most distinct at the time of a deep inspiration. I speak here of the *time* of the inspiration, and not of the assumed passage of air from the pharynx into the sac. When the nostrils were closed, the mouth open, the tongue protruded, and a film of mucus was stretched across (as was often the case) from the tongue to the velum palati, it was interesting to note that the film would persist for an indefinite period, thus proving that no air entered the sac during respiration. Forcible closure of the nostrils would often cause the film to bulge forward and break. I assume that the displacement of the air from the nose had slightly compressed that in the pharynx. The sac was seen to be easily closed by pressure from without, the two lips came together, and the whole space was obliterated. The fistulous track through the wall of the sac was valvular. A probe passed through it was easily discerned in the pharynx. The outer end of the fistula being covered with plaster, and the nostrils and mouth closed, the sac could be distended so as to become convex anteriorly. I assume this was caused by elevation of the base of the tongue and velum, and consequent displacement of the air of the mouth and pharynx downward.

FIG. 1.

Respiratory curves made by motions transmitted by the neck to level placed on sac.

The respiratory phenomena, although not subjected to precise experiment, appeared to be normal. The patient breathed from nineteen to twenty-two respirations per minute. The chest-expansions were free and unimpeded. A tambour being held in contact with a lever placed on the sac, and so arranged as to transmit impulses to a second tambour so disposed as to have its movements recorded on a kymographion, was found to make a downward

[1] A report of an investigation made at the instance of the College of Physicians of Philadelphia, and presented March 7, 1894.

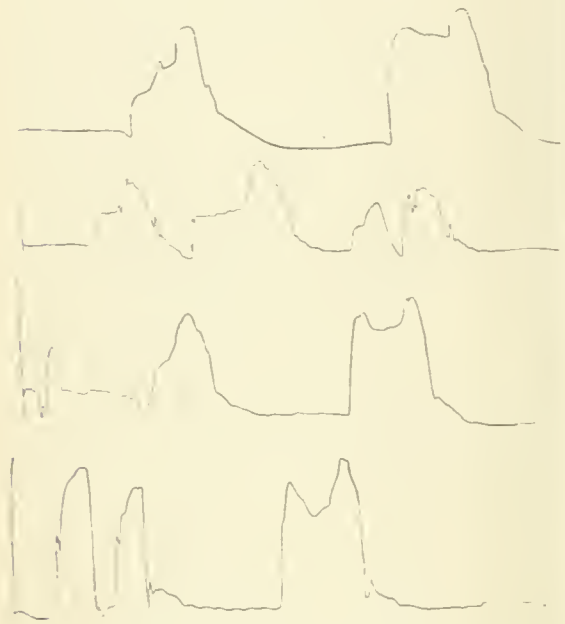
[2] See Trans. Phila. County Medical Society, vol. xiii, 1892, p. 302; also Trans. College of Physicians of Philadelphia, 3d Series, vol. xv, 1893, p. 131.

[3] A brief reference to the operation will be found in THE MEDICAL NEWS of July 23, 1892, p. 98: and a reference to the subsequent course of the case in THE NEWS of February 18, 1893, p. 195.

tracing during the act of respiration, while the form of the sac did not change in shape. I conclude that these movements were secondary. The changes here noted were due to the motions of the neck itself during the act of respiration. and were probably related to the elevation of the clavicles and the upper part of the thorax. (Fig. 1.)

The act of swallowing was performed with comparative ease, though food was apt to pass into the sac. Liquids flowed out readily from the fistula. Pressure on the sac with the finger prevented the passage of both solids and liquids, and this pressure was regularly employed by the man in eating and drinking. The tracing made on the kymographion varied exceedingly, and appeared to be due to inconstant use of the tongue and pharyngeal muscles. Some of the tracings of deglutition are herewith given. (Fig. 2.)

Fig. 2.



Tracings of the variants of deglutition.

The voice appeared to be true, as opposed to a whisper. It was thin, harsh, and weak, though estimated by Dr. Cohen to be heard at forty feet. Wheezy sounds of air escaping from the lung occurred coincidently with speech.

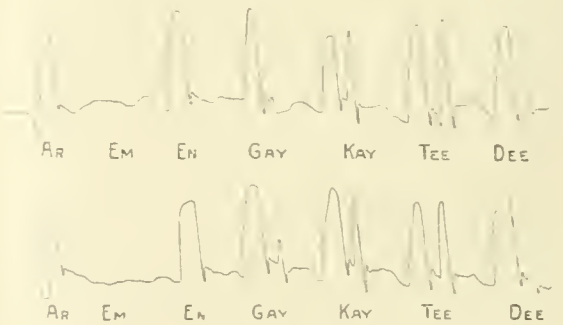
The voice was fairly well modified, and was capable of slight shades of expression. The patient could sing a song, and while the musical character of the performance was *nil*, the difference in tone between the attempt at singing and ordinary utterance was evident.

In studying the phenomena of speech the first experiments were directed to the tongue and velum. I repeated the observations of Dr. N. Kingsley to ascertain after what manner the tongue was used in articulation. I secured the assistance of Dr. W. Christensen, a dentist in this city, who kindly prepared a number of vulcanite plates. Coating one of these with a mixture of alcohol and prepared chalk, and placing it in the roof of the mouth, I directed the patient to pronounce the letters of the alphabet. The tongue wiped away the chalk and exposed the black color of the rubber beneath. It was easily ascertained that the contact of the tongue against the velum and palatal vault was made in a normal manner, the only difference between those thus obtained and those made in the mouth of Dr. Christensen himself being of a character that could be readily explained by individual peculiarity. The patient was rendered mute by the insertion of the plate, but by a little practice the voice returned. The slightest pressure of the plate against the velum immediately destroyed the power of utterance.

The voice was next recorded on a phonograph. This was done with the object in view not only of eliminating the tracheal noises, but of catching the shades of distinction of the voice that could not be detected by the unaided ear. I regret to say that these experiments were without results.

The third series of observations consisted in careful inspection of the sac during enunciation. The following facts were elicited: Just before speaking the patient inspired: then at the time of talking (the pronunciation of definite simple sounds was practised) the sac filled and emptied. The levers with tambours were here used, and their movements were recorded on a kymographion, as in the case of the respiratory movements. All of the speech-tracings were upward, and were thus quite unlike those of respiration. (Fig. 3.) Filling of the sac occurred

Fig. 3



Tracings of consonants *r*, *m*, *n*, *g*, *k*, *t*, *d*—Continental pronunciation.

in all the consonants in which *e* (*i. e.*, the sound made in the English alphabet) entered. *G* (gay) produced, as was expected, a maximum amount of movement in the sac-wall. The least constant movement occurred in *m* (em). While engaged in repeating these sounds it occurred to me that it would be convenient to have a number of phonetic characters arranged in the order of their formation from the throat toward the teeth, and I accepted the following as fairly representative of such a series: *r*, *m*, *n*, *g*, *k*, *l*, *s*, *t*, *d*. All observations were made

with the patient reading aloud these letters from a chart placed in front of him, while the head was supported to eliminate all body-movements. It was soon noticed that the movements in *m* were the least constant, and the sac-movements were influenced by the act of respiration. If a full inspiration were taken, and *g* pronounced and *m* followed, scarcely any motion ensued in the sac, while if, after a full inspiration, *m* was at once pronounced the sac-walls moved almost as freely as in the pronunciation of any other sound. At the same time it was evident that while neither the air of inspiration nor that of expiration was used, the patient could speak only during expiration. I recognized the subject to be complex. The difficulties in maintaining exact uniform contact of the lever against the sac were considerable, and had not been overcome at the time the experiments were interrupted. But this much can be said: that the movements of the sac-wall were freest in the formation of the sound when the base of the tongue is known to assume the largest size (*i. e.*, humping upward), and that they were limited in range or entirely absent when the base of the tongue was known to move upward the least in the manner described; therefore, that the times of enunciation and those of movements of the sac were synchronous, and that a direct connection existed between the movements of the sac and those of the tongue. In a word, the movements of the sac-wall were due to compression of air in the sac, due in its turn to displacement of air in the mouth and pharynx. (Fig. 4.)

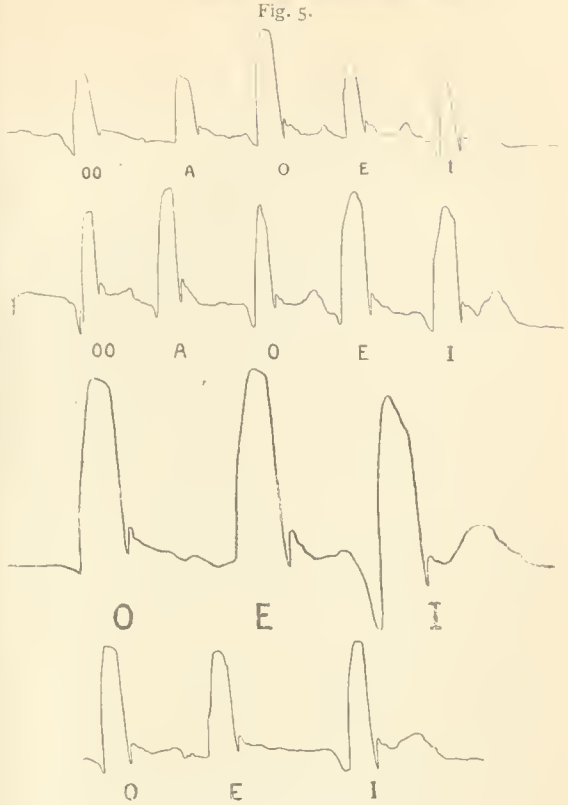
Fig. 4.

Tracings of the same consonants illustrated in Fig. 3. The crosses represent the times of expiration.

Enunciation of the vowels permits air to pass through the mouth through relatively wide apertures as compared with enunciation of the consonants. Among the vowel-tracings I secured, as a rule, a single curve. (Fig. 5.) The variations were sufficient to lead one to suspect that oscillation was a disturbing tor. Yet, when allowance is made for this error, the tracings are seen to be broadly contrasted with those of the consonants, and the semi-vowels *l* and *r* to be (as they should be) quite like the vowels themselves. (Figs. 6 and 7.)

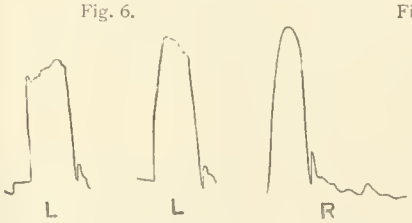
Enunciation of the consonants permits air to pass through the mouth with difficulty, if at all, and we find with them a disposition to form a double tracing, excepting in the case of *m* and *n*. The fact that *n* sometimes has a semi-vowel value probably accounts for its curve being at times like that

Fig. 5.



Variants of the tracings of the vowel sounds. Continental pronunciation.

Fig. 6.



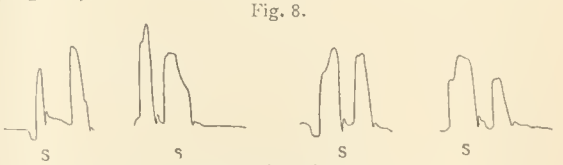
Variants of the letter *l*.

Fig. 7.

Variants of the letter *r*.

of a vowel. Further investigation will be demanded to settle this point. I thought I had secured a uniform, constant value for this letter, but I may have been mistaken. As a rule, it may be said that the greater the resistance to the outward flow of air the more striking become the sac-movements. As can be surmised, these were greater with surds than with sonants, and therefore were greater with *t* than with *d*, and were marked with the sibilant *s*. (Fig. 8.)

Fig. 8.



Variants of the letter *s*.

Stimulated by these observations, I was about to institute a carefully devised series of tracings based

on the tenets of phonology, when the investigation came to an end.

The relation which existed between the distention of the sac and the movement of respiration and in pronouncing *m* remains unexplained, as indeed did the following curious observation: Occlusion of the tracheal opening, care having been taken to avoid any pressure on the sac, at once arrested speech. I tried this experiment many times. Again, occlusion of the sac likewise arrested speech. I unfortunately failed to observe if this could be overcome with practice, as was the case with the use of the vulcanite plate, or whether a whisper might have been developed when the sac was closed.

The views entertained as to the significance of articulate speech make it necessary that a current of air should vibrate against a flexible hem or border. Dr. Cohen informs me that he thought the scar-like band on the posterior aperture of the sac might serve this purpose. I see no reason why this might not at least assist, while the general constriction of the circular fibers of the inferior and middle pharyngeal constrictors might act as the cause of the speech by the air vibrating against lips of muscle-ridges which existed only at the time that enunciation occurred. The motions of the sac were also to be explained by these constrictions and (as already stated) by the tongue. But why the act of respiration is in any way related to the performance of these acts is not apparent, unless we assume that the muscle-movements are part of a complicated mechanism which demands the participation of the respiratory act as well as the pharyngeal and oral mechanisms, even in the accidental circumstance of the laryngeal apparatus being absent.

The hypothesis that at first sight is reasonable, that the sac fills when the lung fills, and that sound is produced while the sac empties itself during expiration, is in harmony with the physiology of normal speech. But I cannot see how this opinion can be entertained if it be conceded that the sac did not fill during inspiration, and that the respiratory act did not affect it any more than it did any other part of the neck. But the movements of the sac were coequal with the time of enunciation, and while influenced in a measure (as in pronouncing *m*) by the act of respiration, were not dependent upon it. The idea that speech may have occurred during inspiration is suggested by the shape of the respiratory curves on the kymographion, but this was at once invalidated by the fact that the tracheal noises of expiration were always synchronous with speech, while the respiratory curve was downward instead of upward.

I venture to express the opinion that the displacement of air from the pharynx by the constriction of the lower pharynx was nearly normal, and the humping of the lingual base absolutely so. That these produced so great a change in the sac of our patient was due to the absence of a check-mechanism, the larynx itself, which thus acts in the norm as a barrier to the retrocession of the compressed air. In health the vocal bands when adducted form an almost complete barrier to the entrance of air, and in order that the bands themselves be spared from pressure, laryngeal ventricles are provided to receive and hold it. Not only is this the case, but, in the act of swallowing, these sacs may also serve a purpose of accommodating the air, which, being pushed in advance of the ingesta, would be thrown into the trachea were not a special mechanism provided. The muscle constrictors at the laryngeal orifice exist for this purpose in health. It is noted that the epiglottis is not spoken of in this connection as a factor, either in speech or as an aid to prevent the entrance of food into the larynx. It is my opinion that if it held such an attitude it would have exerted some influence in protecting the sac against the entrance of both solids and liquids in the act of deglutition.

While making the statement that the patient had voice, it is tenable that it was a voice created by the presence of an adventitious resonating chamber established in the region of the larynx, and that the utterances were of the nature of whispers reinforced by the air in this sac.

A BRIEF SPLINT-TECHNOLOGY FOR SURGEONS.[1]

By EDWARD A. TRACY, M.D.,
of Boston;
Fellow of the Massachusetts Medical Society.

The objects of this paper are to treat in detail of a new material and method devised for surgical splint-making; to aid the surgeon to become the maker of suitable splints for cases occurring in practice; and to indicate lines of procedure in apparatus-making that promise rich results in general and orthopedic surgery.

The Material.—The basis of the material employed is wood-pulp, made preferably from the crushed fiber of the poplar tree, and rolled in such fashion that the broken fibers intertwine in every direction and loosely, so that an increase of plasticity is thus given to the product. These sheets are further strengthened by having a fabric introduced between the layers of the pulp, or by interweaving with the short, crushed wood-fiber, a long jute or other tough fiber.

The sheets are rolled of different thicknesses, for adaptability to all splint-conditions. For convenience I shall designate the thickness by number,

[1] An abstract of a paper read before the first Pan-American Medical Congress, at Washington, 1893.

each unit representing a thickness of one millimeter; thus, sheet 1 represents the material with a thickness of one millimeter; sheet 2, with a thickness of two millimeters, and so on.

Characteristics of the Material.—The chief characteristics of this material are stiffness or rigidity when dry, and plasticity when moist. Its rigidity can be increased *ad libitum* by the use of a silicate solution as a moistener. Its plasticity has a limit. The limit is rarely experienced and only when molding the material over certain complex curved surfaces. To exemplify: A splint cannot be directly molded over the ankle-joint anteriorly, for there are two large curves in opposite directions to be followed simultaneously, the convex curve from malleolus to malleolus, and the concave curve from above downward over the leg and instep. This difficulty, when met, can be obviated in various ways. I shall mention three of them. Take the case of the ankle-joint: An anterior splint is required for it. The proper-shaped blank should be cut from sheet No. 1 and moistened with one of the solutions to be described later. It should then be applied to the limb, care being taken to keep its outer border in contact with the skin, while the superfluous material over the anterior aspect of the joint should be pinched between the thumb and forefinger, and all of it laid or pressed over to one side; a bandage should be snugly applied to perfect the molding of the splint. (This method of "pinching and folding over" has an important application in the making of spinal jackets.) A second way consists in cutting away the superfluous material, in this case an elliptic figure, and bringing the edges of the cut portion together, and so retaining them by means of a strip of the material pasted over the cut edges. A third method is to cut a blank for each important curve and, after molding, to properly unite them.

Besides the foregoing characteristics, the material possesses that *desideratum* of a splint-material—extreme lightness. Its cheapness also deserves a passing mention.

Moisteners.—Water or a stiffening solution can be used to moisten the material. The advantage of water is its omnipresence. A serviceable splint can be made with its help. Such a splint should be protected from perspiration or other moisture, lest it be softened and its usefulness destroyed. It can be so protected by a covering of oiled paper or silk, by mackintosh, or best by a coat of varnish.

A stiffening solution, with several qualities to recommend its use, is that of silicate of potassium; silicate of soda is almost as serviceable. Any desired degree of rigidity can be imparted to a splint by using this solution—the amount of rigidity depending on the strength of the solution. A splint rendered rigid in this manner is not affected by perspiration, or indeed by momentary contact with fluids, as in washing. Another advantage, especially in cases of compound fracture, is that this solution renders the splint antiseptic.

In practice, the solution of silicate of potassium generally sold for surgeons' use, and further diluted with water, can be employed. The commercial solution is regarded as a 100 per cent. solution, and the percentage solutions spoken of in this paper are to be made by diluting the commercial solution with the proportion of water called for by the percentage; thus a 70 per cent. solution is made by mixing 70 parts of the commercial solution of silicate of potassium with 30 parts of water. The commercial solution should have a specific gravity of from 1.3 to 1.4.

Another useful stiffening solution is that of dextrin, in the proportion of about ʒviij to Oj of water. This solution adds some tenacity, besides stiffness, to the material treated with it. A splint made with its aid can be remoistened with water and remolded—quite an advantage in cases in which, from disappearance of swelling or other cause, a closer approximation of splint and limb is desired. In practice, dextrin (to be had of paint-wholesalers) can be carried in powder form, and a solution in water extemporized when needed. (An addition of 8 gr. of corrosive sublimate to Oj of the dextrin solution will render it antiseptic.)

Moistening Process.—A few descriptive words should be added concerning the proper manner of moistening the material. The aim should be to get barely sufficient moisture into the material to render it semiplastic. If more moisture be absorbed, it becomes more difficult to maintain the molded splint in the desired shape while drying, and it also unnecessarily lengthens the time required to dry the splint. I find the best manner of moistening the splint-blank is to apply the fluid used, on each side of it, alternately, by means of a flat paste-brush. A little practice will enable one to judge the precise amount of moistening best suited for the purpose.

Drying. — The time required for drying the molded blank varies, for the different sheets employed, from ten to forty minutes; the thicker sheets, holding the more moisture, require a longer exposure to heat. Any source of sufficient heat can be employed; a good kitchen fire is very efficient and, generally, convenient. While the splint is drying it is serviceable to have yarn or string wound around the moistened form after its removal from the body, to aid it to maintain the desired form, until permanent drying fixes it.

I shall briefly consider the application of splints to the human body, under the headings—

1. Head splints.
2. Trunk splints.
3. Upper limb splints.
4. Lower limb splints.

This simplicity of classification will necessarily be violated in specific cases in which compound splints, embracing parts of different systems, are constructed.

[The following four descriptions are selected from the original paper for illustration in this abstract.]

1. A CERVICAL SPINE SPLINT.—This splint is devised for fixation of the cervical vertebræ. The blank is cut from sheet No. 2 or from sheet No. 3, according as the case is that of a child or an adult. The head of the patient should be supported in the desired position while the moistened blank is being molded over the back, shoulders, neck, and occiput; the molding is facilitated by the use of a gauze bandage applied snugly over the blank. After a short retention the molded blank should be removed and dried. The neck-piece can be reinforced if desired. The complete splint is pictured in Fig. 1.

FIG. 1.

A cervical spine splint.

2. A SPINAL JACKET.—I shall here briefly suggest a technique for a simple, cheap, and serviceable jacket.

The blank is to be cut from sheet No. 1 and moistened with a 75 per cent. solution of silicate of potassium. This blank is of the simplest pattern, being sufficient to envelop the patient's body, once and a quarter around, and its width governed by the amount of spine we desire to control. The needful trimming of the blank can be done upon its first application to the body. The patient should be placed in the same position as for the application of a plaster jacket; he should have on him a tight-fitting woollen undershirt. The blank is to be applied to the body by commencing on the front about two inches beyond the median line, and keeping that portion in place, guiding the rest of it around the body so as to overlap considerably in front. A vertical line should be drawn on the overlapping piece, from the armpit; the object of this line is to give position to the hinge-joint which we require in the jacket to facilitate removal and reapplication. The joint is made by bending the moistened blank backward and forward along this line until the pulp is sufficiently broken—the fabric imbedded in the sheet forming the hinge. After drying the jacket, this hinge should be strengthened by gluing strips of chamois skin, one inch wide, over the hinge, inside and outside.

FIG. 2.

A spinal jacket.

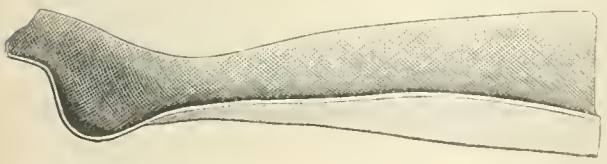
The blank having been applied to the body as described, we proceed to make it conform to the body-surface as accurately as possible. We place over the spines a large pad (two large rolled bandages, each four inches in diameter and six inches long, placed end to end, do well), which serves to press the blank well into the hollow of the back. Further conformation to the body is obtained by the "pinching and folding over" method described. Here this method is particularly advantageous, for it adds threefold to the vertical strength of the jacket, without a material increase of its weight. A gauze roller-bandage should be so applied over the whole blank as to hold it in snug apposition to the body. After a few minutes' retention the bandage should be taken off and the jacket carefully removed; in doing so the hinge described should be made use of, so as to disturb as little as possible the form imparted to the jacket. If the blank has been properly moistened, but slight aid to hold its form need be given to the jacket, till drying permanently fixes it. Thus, the foundation for a good spinal

jacket is completed. It can be reinforced as desired. Straps can be fastened to it for its adjustment, or lacing bands can be applied to it for the same purpose. Fig. 2 illustrates a spinal jacket which was molded on and worn by a boy of six years. The binding and fasteners are made of chamois skin, glued by means of a cheap liquid glue directly to the jacket. The hinge-joint is here omitted, the natural resiliency of the material sufficing for the removal and reapplication of the jacket. The jacket was made at the child's home in about forty minutes.

3. A Palmar Forearm Splint.—This is a very simple but important splint. It meets the indications that Cheever emphasizes in the treatment of a Colles' fracture. That accurate surgeon says: "The important point would seem to be . . . . not to press the back of the wrist down in such a way, by splints, that we shall lose sight of this arch, which is so marked, under the radius. . . . . This arch must be well supported. . . . . The splint should terminate at the head of the metacarpal bones, and the thumb and fingers should be left free.[1]"

The position of the forearm for the splint pictured in Fig. 3 was that of semi-pronation; that of the wrist, semi-extension—its natural position of rest. The pattern should slightly overlap the ulnar side of the forearm, so that there will be sufficient material in the blank to be molded over that side of the forearm. The blank should be cut from sheet No. 1 and moistened carefully with a 75 per cent. solution of silicate of potassium. The blank should be applied to the palmar surface of the forearm, so that the ulnar side is overlapped by the blank. The

Fig. 3.



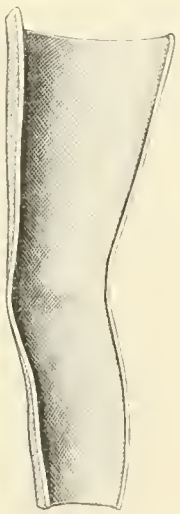
A palmar forearm splint. (Right, viewed from radial side.)

blank should then be carefully molded over the forearm in the position described. After snugly applying a roller bandage over the splint, commencing at the wrist, then enrolling the hand, and finally the arm, pressure should be applied by squeezing the forearm and splint between the thumb and fingers at a point one inch and a quarter above the styloid process of the radius, where the arch of the radius is most pronounced. The direction of the pressure, it need hardly be mentioned, is from the palmar to the dorsal side of the forearm; its object is to give the splint an arch approximating that of nature. After squeezing in the manner described for a moment, the splint should be removed and dried. A side or radial view of the completed splint is pictured in Fig. 3.

The curve of the splint caused by the arch of the radius is there imperfectly illustrated. The curve of the splint, made by molding the overlapping portion of the blank over the ulnar side of the forearm, is important, because it is the main source of the strength of this splint.

4. A Latero-posterior Knee Splint.—This splint is for fixation of the knee-joint. It is a modification of the so-called ham-splint. It differs from the ham-splint in having a surface that is applied to the lateral surface of the limb (preferably the inside), as well as to the posterior aspect. This

Fig. 4.



A latero-posterior knee splint. (Left.)

addition greatly strengthens the splint and aids its fixation. The blank should be cut from sheet No. 2 (sheet No. 3 for a very powerful limb), and moistened with a silicate solution. The blank should be applied to the limb so that the portion corresponding to the shaded part of the pattern lies over the internal aspect of the limb. The molding of the splint is perfected by applying a roller bandage snugly about it; after a moment's retention to the limb the splint should be removed and dried. A completed splint for the left knee is pictured in Fig. 4.

THE COMMERCIAL FORMS OF HYDROGEN DIOXID.

BY HENRY LEFFMANN, M.D.,
OF PHILADELPHIA.

ABOUT about two years ago (MEDICAL NEWS, April 9, 1892), a note was published by Dr. Beam and myself on the analysis of some samples of hydrogen dioxid, the brands selected being such as were in common use. The figures showed that considerable difference existed between the articles, and that some brands were decidedly inferior, both as to strength and purity. Similar investigations have been reported by others. Thus Dr. Smith, of the Yale Medical School, published in the *New York Medical Journal* of August 6, 1892, a table of analyses of many samples purchased in small amounts at retailing drug-stores. The maker's name was obtained when possible. These analyses showed much variation in quality, but the manufacturers may not be responsible for all the deficiencies observed. Some samples were found to contain no hydrogen dioxid, and others very little. The same issue of the *Journal* contains a paper by Dr. Squibb, discussing the method of assay, and giving the results of examinations of some much-used brands as sent out by the makers. Dr. Squibb gives figures only for the strength in available oxygen, but he states that several brands contain much more free acid than is either necessary or permissible. In the last number of *The Ephemeris* (January, 1894), Dr. Squibb details an elaborate study of the preparation and properties of the dioxid, but the information concerns the chemist and pharmacist rather than the physician. The papers of Drs. Smith and Squibb confirm, as far as they cover the same ground, the figures given by Dr. Beam and myself. It has seemed advisable to repeat the analytic tests, to determine if any perceptible improvement in the quality of the commercial articles has followed the publication of the analytic reports.

Incidental to the discussion of this subject, it has been shown by Dr. Squibb that a process for the assay of hydrogen dioxid, furnished by Mr. Marchand, and adopted by many, gives erroneous results, exaggerating materially the value of the sample tested. Correct methods of assay show that no solution is ordinarily obtainable in the market of higher strength than twelve volumes, and that many do not equal this. When properly prepared these solutions are not nearly so liable to decomposition as was formerly supposed. They keep for some time in a moderately cool place, and will bear gentle heating without serious loss. Many of the samples herewith noted were kept in my laboratory for several weeks at a point where the temperature was in the neighborhood of 70° F., the corks being not very tightly inserted, and a second determination was then made, the results of which are given in the table appended. It will be seen that there has been little loss, and, indeed, slight concentration has occurred in a few cases. This has been noted by others, and is due to the fact that hydrogen dioxid is less volatile than water.

One of the points indicated by the results is that reputable manufacturers should cease claiming a strength of fifteen volumes. The use of these figures may have been originally due to the employment of the erroneous method of assay noted, but there is now no justification for continuing the error, as the United States Pharmacopeia gives a correct process. On the other hand, there does not appear to be any reason that the article should be sold to the trade without some indication of strength. Many samples were found to be sufficiently decomposed when purchased, even when sent directly from the place of manufacture, to produce marked explosions when the corks were loosened. This must be considered an unfavorable point, as a good eleven-volume solution may be made that will not be so easily decomposed.

Some interest attaches to the amount and general nature of the impurities present, and determinations of a few of these have been made. It is not possible, at least not commercially practicable, to make a solution consisting of water and hydrogen dioxid only, and the material will not keep without a trace of acid. The acid is usually either sulphuric, hydrochloric, or phosphoric, and according to the standard of the United States Pharmacopeia it is required that barium shall not be present. Squibb asserts in the article in *The Ephemeris* that barium is highly objectionable, though I am not able to see how a small quantity can do harm. Only one sample of all examined by me gave a reaction for barium, and a quantitative determination showed that this sample contained 35 milligrams (about half a grain) to the liter. I cannot regard this amount as objectionable in any way. The sodium hydroxid solution used was a little weaker than decinormal.

The following table shows some very interesting points. In the first place, it is not surprising that satisfactory results are sometimes not obtained with the agent. The poor quality of Nos. 5 and 6, both from the same manufacturer, but obtained through different wholesalers, is especially noticeable. The specimens are little else than dilute sulphuric acid. Nos. 15, 16, and 17 are accompanied by a circular claiming great purity and strength, and especially claiming only a trace of fixed residue; yet it is seen that the residue is the highest of the series. These samples were all from the stock of a large general hospital, to which they were furnished by the makers as specimens.

BRAND.	Volumes of oxygen.		C.C. of NaHO for 50 c.c.	Residue from 50 c.c.	Pressure on opening bottle.	Response to test for

14. Lehn & Fink	3.7	3.6	19.0	0.120	Marked.	Slight.	Marked.
15. Pouchet	8.0	7.0	0.363	Strong.	"	"	
16. "	....	8.2	8.0	.....	"		
17. "	.....	8.8	8 5	0.358	"		
18. Squibb & Son	11.1	10.8	10.5	0.111	Very slight.	Slight.	Marked.
19. Drevet	8.2	7.6	7.5	0.059	" "	"	"
20. Smith-Klein-French Company	7.5	7.3	20.5	0 108	None.	Marked.	"
21. McKesson & Robbins	.....	10.0	2.2	0.031	"	Slight.	None.

It is hardly necessary to point out the other details of the table, but as an evidence of what can be accomplished I would like to call attention to the low acidity of Nos. 1 and 21, which show full strength and excellent keeping qualities.

The analytic investigation shows, therefore, that while there are several excellent brands of hydrogen dioxid on the market, there is still a great deal of inferior material, and that the reputation of a manufacturer is no assurance of quality. When it is considered that the assay of this material is easy, and its stability when properly made is satisfactory, it seems that the physicians and pharmacists have a right to require that at least a ten-volume solution, containing only a small amount of acid and of solid matter, shall be furnished. Moreover, there is no excuse for a druggist dispensing a weak preparation. He can exercise with but little trouble a control over his purchases of hydrogen dioxid, and a bottle once tested (only 1 c.c. is required for a test) can be kept so that very little loss of strength occurs during a reasonable time.

Actual trial by prescriptions at two drug-stores, one in the center of the city and the other in the northeast section, resulted in obtaining very satisfactory samples, each showing nearly eleven volumes.

Some very poor samples, in one-ounce bottles, have been obtained from special supply-houses (not dealers in drugs), but the data in regard to these will be published elsewhere.

Solution of hydrogen dioxid may be concentrated upon a water-bath to a strength of fifty volumes or more. A smooth dish should be used, and the liquid be protected from dust, for, as Squibb has shown, any rough surface promotes decomposition. Judging from the rapid evolution of gas which occurs when solutions are heated over even a low-temperature burner, it is necessary to use a water-bath. Freezing may also be used to concentrate the liquid. Tight corking does not prevent decomposition, and the practice of wiring corks leads to dangerous pressure in the bottles. I have noted in the table the existence of marked pressure in some samples, and most of these produced, on releasing the cork, a violent noise which would be decidedly distressing in the sick-room, in addition to being an indication of imperfect preservation.

[1] Contains 35 milligrams of barium per liter.

HYSTERECTOMY FOR OTHER CONDITIONS THAN FIBROID AND MALIGNANT TUMORS.[1]

BY CHARLES B. PENROSE, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

UNTIL very recently the operation of hysterectomy was confined practically to two conditions, malignant disease and fibroma. The improved technique and the admirable results obtained in the modern operation for these conditions have led to its extension to other diseases of the uterus and the appendages. The most radical proposition is: to remove the uterus in every woman in whom it is necessary to remove the uterine appendages. A second less radical proposition may be thus stated: In any case of pelvic disease when there is necessary for cure an operation on the appendages that renders the woman sterile, hysterectomy is a valuable addition to the operation under the following circumstances: when the uterus is diseased; when it is likely to become so; when its removal will facilitate the operation.

[1] Read before the College of Physicians of Philadelphia, March 7, 1894.

I have been following this latter plan since June, 1893, and wish to report my results and conclusions to the Fellows of the College with the object of obtaining their views upon this new plan of treatment.

The number of cases is not large, but represents a variety of conditions. In a series of seventy-five celiotomies on women for different forms of pelvic disease, exclusive of fibroid and malignant tumors, I have found it of distinct advantage to remove the uterus in fifteen cases, which may be grouped under the following headings:

I. Cases of double salpingitis, generally pyosalpinx, the disease extending into the uterine cornua in the form of a hard cheesy nodule, or an abscess in the uterine tissue; large uterus, chronic metritis and endometritis; profuse irritating vaginal discharge, probably gonorrheal.

II. Cases of salpingitis and ovaritis; flexed or displaced uterus, with or without adhesions; endometritis.

III. Salpingitis of which tuberculosis is the probable cause.

IV. Cases of ruptured tubal pregnancy, of pelvic abscess, or of any accumulation in the pelvis in which the uterus forms part of the wall surrounding the accumulation. The removal of the uterus facilitates the operation and perfects hemostasis.

It must be remembered that in all these cases the uterus was removed as an addition to an operation which rendered the woman sterile. I think that we can consider that the removal of the Fallopian tubes renders the woman sterile, except in very rare instances.

The gonorrheal cases form a large class representing the most frequent form of salpingitis, and in this disease I think that hysterectomy is a valuable addition to the old operation of simple salpingectomy. In several of the gonorrheal cases my determination to perform hysterectomy was based on the fact that gonococci had been found in the discharge from the os uteri. In others the history of the case and the presence of gonorrheal lesions, such as inflammation of the vulvo-vaginal glands, or their ducts, or urethritis, indicated the gonorrheal origin of the disease, and finally in other cases gonococci were sought for by an assistant in the tubal contents during the operation.

In cases of gonorrheal pyosalpinx the old operation of removal of the tubes relieves the woman from the danger of rupture into the peritoneum. But it does not cure her. The disease continues in the endometrium and in the deeper structures of the uterine wall, often extending from the tubes into the uterine cornua. Careful operators have in these cases been in the habit of removing, by a wedge-shaped amputation, the proximal end of the Fallopian tube. This operation, however, requires almost the same length of time as hysterectomy, and is not followed by perfect hemostasis.

The operation of hysterectomy, however, cures the woman of the leukorrhea which is often the symptom of which she complains the most.

I have tried by all the means devised to cure gonorrheal endometritis, with but very unsatisfactory results. I have never cured it in a case in which pyosalpinx had coexisted. If we leave the uterus in these cases the woman continues to have an irritating infectious discharge, and she is not considered cured by herself or by her husband.

In posterior displacement, with salpingitis and adhesions to the fundus uteri, removal of the uterus gives more promise of cure than simple removal of the tubes. It is a mistake to suppose that the posterior displacement will remain corrected by the tension of the broad ligaments following a simple salpingectomy. In one case in my series the tubes and ovaries had been removed some years before my operation, and yet the uterus was in a position of extreme retroversion, and the pressure of the fundus upon the rectum caused such pain that for some months before the operation every movement of the bowels had been preceded by a hypodermatic injection of morphin. Hysterectomy stopped the pains and the morphin-habit.

In tuberculous disease of the tubes I think that hysterectomy should always be performed. The investigations of Williams (*Johns Hopkins Hospital Reports*, vol. iii) show that in this disease the uterus and endometrium are affected in from 40 to 60 per cent. of the cases. Unfortunately it is at present impossible to determine the tuberculous character of many cases of salpingitis by the gross appearance at the time of operation, and we are unable to determine the full extension of the disease.

In a case of salpingectomy performed last November the microscope showed tuberculous infiltration in the tubes extending to the plane of section. Had I known this at the time of operation I would have removed the uterus.

In one case of suspected tuberculosis I curetted the uterus and examined the scrapings before the operation and then performed hysterectomy on account of the probable tuberculous character of the endometritis.

The fourth class of cases in which the operation is facilitated by the addition of hysterectomy is illustrated by a case of ruptured tubal pregnancy. The woman had a ruptured tubal pregnancy on the left side. The pelvis was filled with old blood-clot which was walled in by adherent intestines above and by the uterus and broad ligaments in front. The abdominal ostium of the right tube was closed,

and the tubes and ovary were bound down by adhesions. In this case the removal only of the blood-clot and as much of the sac as was practicable would have left behind a large bleeding uterus destitute on two-thirds of its surface of any peritoneal covering—and functionally useless when the tubes and ovaries were gone on each side. Its removal, however, enabled me to secure quick and complete hemostasis and to avoid an elaborate drainage of the pelvis.

I know of no way in which the removal of what has been called the emasculated uterus injures the woman. The results in large numbers of hysterectomies for carcinomata and fibromata show that from the mechanical and functional points of view the remaining pelvic contents are uninjured.

Unlike the ovary, the uterus does not seem in any way necessary for the maintenance of womanly traits. I think that, in cases of salpingitis requiring treatment which renders the woman sterile, the removal of the uterus along with the tubes does her less harm, from a psychologic standpoint, than the common operation of removing the ovaries with the tubes. I think that the ovaries, or parts of them, should be left in all cases where practicable, especially in young women.

An objection urged against this form of hysterectomy is the increased danger of the operation. It is undoubtedly true that in some cases the prolonged time of operation, even if only ten or fifteen minutes, may be of serious harm to the woman. In such cases I consider that the operation is improper. The determination to remove the uterus in the class of cases under consideration should depend upon the condition of the woman when she is on the operating-table. If her condition is such that she can endure the increased operation, then I think that hysterectomy is a valuable addition to our treatment in all cases of tubal and ovarian diseases requiring an operation which renders the woman sterile, provided that the uterus is itself diseased to such an extent that it will not readily yield to local treatment; or is so implicated in the pathologic condition in the pelvis that its removal facilitates the performance of a complete operation.

The statistics with which I am familiar show that the removal of the uterus under these circumstances is attended with as small a mortality as the operation of salpingectomy. All the cases in my own experience have recovered.

Dr. William Leishman, until recently Regius Professor of Midwifery in the University of Edinburgh, died February 18th, aged sixty years. He was the author of a *System of Midwifery*, which passed through four English and three American editions.

CLINICAL LECTURE.

OSTEITIS—FISTULA IN ANO—GOITER—HYGROMA—CARCINOMA OF THE STOMACH—SEBACEOUS CYST—RACHITIS, GENU VALGUM—CONGENITAL TORTICOLLIS—ANKYLOSIS OF THE ELBOW-JOINT WITH DISLOCATION OF THE RADIUS.

By JOHN B. HAMILTON, M.D., LL.D,
OF CHICAGO;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY, RUSH MEDICAL COLLEGE.

[Stenographically reported for THE MEDICAL NEWS.]

OSTEITIS.

This patient comes to us from a distance, having cicatrices above the knee-joint on the inside of the femur, and a fistulous opening beneath the joint, with a history of having had several abscesses from which small exfoliations of bone have been removed. At these times he has had great pain. At the present time the inflammation has diminished and the sinus is reduced to a small size. Shortly after the tract thus healed pain and swelling set in and continued until an abscess formed, burst, or pointed either in the old tract or somewhere adjacent to it, and he is at present thus somewhat relieved. Such a history can only point to continuous bone-disease of some kind. The pain and the history show us the cause of these repeated abscesses. If we can keep this sinus open continuously it might discharge itself, and the pus formed would be drained without the formation of this collection of matter about the bone. When this fistulous tract is obstructed, the abscess begins to redevelop and the pus-microbes increase.

We will now investigate the condition of the bone. In the popliteal space we see an old opening which is now almost closed. A little anteriorly, on the lateral surface of the thigh, we find an open sinus. I will pass a probe into it and endeavor to reach the seat of the abscess. These old abscesses and long-continued fistulous tracts, having a history like the present case, are very seldom straight; they are almost always tortuous, and the opening that leads to the bone is found in a different direction from that portion of the surface where the fistula is seen. The probe does not reach the bone, but passes into the intermuscular septum. The pain complained of by the patient is not in a place where there is an opening or fistulous tract. I think best to open the fistulous tract as fully as possible, in order to trace and follow it until I reach its ultimate point. I find the tract passing posteriorly to the femur, but doubtless coming from the other side. We will therefore make an opening on the anterior portion of the bone with a view to reaching it more directly and by following this tract. I shall select here the border of the quadriceps. You notice the separation between the muscles. I have dissected down between the intermuscular septum so as to reach the bone. I shall now separate the tissues carefully and inspect the surface of the bone, which is, as I suspected, in a morbid state. The periosteum is diseased. I incise it and come directly down upon a small abscess which you see underneath the periosteum. The bone is denuded at this point and the periosteum separated from it, and here you

notice the beginning of the abscess. We shall now follow the sinus, and we find we can pass underneath the periosteum, which we lift with Kocher's director as it is separated from the bone. We find all of the bone in this vicinity suffering from inflammation. If you will listen attentively for one moment you will hear a hard ringing sound of extreme density when I strike the bone—a sound which cannot be emitted on striking natural, healthy bone. This portion of bone which I touch with the director is practically dead. It has become hardened or eburnated in the progress of the disease.

As I trace downward, I find that, at a point about an inch and a half below, the periosteum again becomes attached to the bone. I shall now chisel away this eburnated portion of the bone, and thus hasten the natural process of repair. The portions of bone now being removed are almost devoid of life. It would be but a short time before there would be separation of this necrosed from the living bone, which has already begun to grow about it, and by being incased we would have a sequestrum formed. This sequestrum would have to be absorbed or taken away by the slow process of Nature—a year or two, or even more, being required to accomplish the process. We may hasten it very materially by chiselling the bone away. Dead bone is simply a foreign body, and can serve no useful purpose in the animal economy. By waiting a sufficient length of time Nature would accomplish the result we are now trying to effect almost without operation, but we can accomplish it much more quickly and effectively by operative measures. I have now cut through the shell of dead bone, and the bone adjacent is osteoporotic, as must be expected from the steady inflammatory process that has been going on in this vicinity. We will now flush the wound with water so as to remove any spiculæ that may remain, and then pack it with iodoform-gauze. Iodin has been added to the water which we are about to use, and I shall see that it penetrates every portion, not only of the diseased surface, but the fistulous tract through which pus has been making its escape to the surface. We will now pack the wound with iodoform-gauze, then turn the patient on the side and scrape out with the curet all old granulation-tissue which, if allowed to remain closed up, may possibly become a pyogenic center. If the opening in the bone were more extensive I might use the bone-chips first brought into prominence by Professor Senn, but in so shallow a wound it is not necessary to use them. The object of the decalcified bone-chip is to afford a framework for the new granulations to rest upon, so that the tender granulation does not break down during the process of repair. It answers the same result as a sponge when it is properly rendered aseptic and introduced into such spaces. We accomplish the same purpose in smaller wounds by the introduction of iodoform-gauze. This has also another effect, that of preventing the oozings that not infrequently follow an operation of this character.

I shall now scrape out all of the granulation-tissue from the edge of this fistulous tract down to its point of origin, and while so doing irrigation will be maintained in order that the débris may be washed out. I will now unite the wound and shall expect primary union. You will notice that I push the knife horizontally under the edge of this incision so as to free the skin from the old cicatricial tissue, which is done in order that it may unite easily without tension and secure perfect apposition of the edges of the wound; otherwise we would doubtless find that the cicatrix would interfere with the process of repair. We will now apply a bandage to the knee and then take off the Esmarch. If I were not perfectly sure no important vessel had been cut I should take off the Esmarch before closing the wound, but I am certain none has been divided by the knife. I have followed in the line of the cicatrix and know there can be no hemorrhage resulting from this wound, but before we remove the Esmarch we will put pressure on it by a compress made of iodoform-gauze.

FISTULA-IN-ANO.

This patient is one that I have not yet examined, but I understand he has some disease of the rectum which is quite painful. I saw him a short time before the clinic and found that it was impossible to examine him until he became under the influence of ether. Externally there are some small projections. I find, on close examination, an opening in one of these projecting points. Following it as far as I can with the probe, and with the index finger of the other hand in the rectum, I find that the probe passes directly into the anus, and therefore recognize that we have to deal with a fistula-in-ano. I will search one of the other points. I also find a small hemorrhoidal tumor. I now examine the mucous wall farther up in the rectum, and finally I pack the rectum with gauze in order that the fecal matter may not obscure the operation. We then irrigate the rectum with sterilized water. We will now pass in a grooved director, then cut out this anal fistula. The operation is easily performed. I now examine the tract for other branches of the fistula, as these fistulæ are very apt to extend around the bowel, and the peculiar condition of the parts leads us to believe that we have to deal with a fistula of that sort. It constitutes what is known as a horseshoe fistula, because it traverses the circumference of the bowel in the shape of a horseshoe. If you simply cut one opening, you do not entirely remove all of the diseased portion, and a "relapse" occurs, to the disgust of the patient. I find the anterior mucous wall very much diseased and studded with soft hemorrhoids. At the verge I shall simply remove these tumors, touching them with the Paquelin cautery at the same time, to prevent hemorrhage; and searing the wound with the cautery, I bring the surfaces together, so as to secure primary union, if possible. I have previously cut out the entire fistulous tract and seared it with the cautery. I shall bring the edges together and unite them. The gauze is removed, and we now insert a large, but short, rectal tube, which you notice is of rubber and has iodoform-gauze wrapped around it. The tube is inserted in order that gases and fecal matter may pass through it. This prevents undue contraction of the sphincter muscle, and at the same time allows pressure from within, so as to prevent hemorrhage, which might otherwise occur.

GOITER.

We have here the commencement of a bronchocele or goiter. You notice the swelling extends to the right of the left sterno-cleido-mastoid muscle. The patient has had some applications of iodin made to the front, which

have blistered the skin, and from which she has just recovered. These goitrous enlargements are quite common in this vicinity. They have been treated by injections of carbolic acid. I am firmly convinced, after watching its effects for two years, that extirpation affords the shortest, if not the safest, remedy in these cases. We may extirpate the entire thyroid gland at one time, having in mind myxedema, a condition which is always to be avoided, if possible, by partial extirpation; at the same time the cases of myxedema occur most frequently in those localities where cretinism prevails without the operation. I do not believe it has been clearly proved that myxedema invariably follows extirpation of the thyroid gland. In some cases I have removed one-half of the gland, and in others the entire gland, and have yet to see a single case of myxedema following it. In view of the present state of surgery, it would perhaps be wise to leave a small portion of this gland.

HYGROMA.

We have here a small tumor on the side of the neck, soft, elastic, non-fluctuating, attached to the skin, apparently not glandular, a little painful, and which has existed since last May. I said painful—I mean painful under pressure, because the patient winced at the time of the examination. I shall explore it with an exploring-needle. The point of the needle is followed by watery blood only. The tumor does not contain pus, and is probably one of those small hygromas or watery cysts attached to the cervical fascia. They should be carefully distinguished from branchial cysts, which are deep in the branchial clefts. They are comparatively easily removed, and I proceed to the immediate removal of this one.

CARCINOMA OF THE STOMACH.

This patient was before the clinic about three months ago. He had at that time symptoms of carcinoma of the stomach, and I advised him to enter the hospital in order that we could, by colonic flushing, remove the fecal matter from the colon, diminish the tenesmus, and then by careful observation make a more accurate diagnosis than was possible at that time. However, I made a rough judgment at that time that he was suffering from carcinoma, and that the disease would progress. I find now a very distinct tumor, and there can be no doubt about the nature of the disease. I will map it out by percussion. You will notice that when I reach a certain point there is entire flatness. My hand is away from the tumor. See how resonant the intestine is where it is healthy. Placing my finger over the swelling, I can map out the colon where it becomes charged with fecal matter. Near the sigmoid flexure we find dulness again; over the surface we found resonance. The patient vomits daily, two or three hours after eating. He tells us that he eats very little solid food, and emaciation is now in rapid progress. Here the pylorus is involved and probably also the duodenum. It is usually stated that carcinoma of the stomach, or a tumor of the stomach, is accompanied by vomiting whenever it affects the pylorus. There is usually no vomiting when the greater curvature alone is involved. When there is obstruction to the outward flow of material from the stomach, then there is regurgitation and vomiting. The rough diagnosis made two months ago is confirmed now, and in a very little while cachexia will begin to show itself in the general appearance of the patient. I would still advise the man to go into the hospital and prepare himself for a gastro-intestinal anastomosis which can be made, and which will somewhat prolong his life.

SEBACEOUS CYST.

This patient has a tumor at the left of the right nipple and at the right of the border of the sternum. The skin is quite red, in a state of inflammation, and is almost ready to break down. On pressure I find it fluctuates. It is about the size of an English walnut, and we learn that it has existed for a period of two years. I have not asked the question, but I should think it is not painful. It is painless, the patient says, although he complains of a little smarting from the effect of rubbing of the clothing on the tumor. The tumor has the feeling of soft cheesy material, and I have no doubt that it is a sebaceous tumor, the same as the sebaceous tumors that occur on the scalp. In this case it is on the breast. Here, as elsewhere, the cause of the tumor is due to the retention of sebaceous material in the duct at the root of the hair. It is a true cystic tumor. The duct becomes dilated by reason of the retention of the natural fluids in the duct.

The patient will now be prepared, and we will proceed to remove it by incision. I find it is confined to the skin, it is movable, and it will not therefore be necessary to go very deeply into it. The tumor can be removed in two ways, either by an elliptic incision including all of the diseased structure, or by a simple incision directly over it, turning out the sebaceous contents and then tearing out the sac from the underlying tissues with forceps, which is one of the easiest ways of removing a sebaceous cyst. The tumor is non-malignant. Here I am able to enucleate the tumor entire, with its capsule, with the handle of the scalpel. We now suture the little wound and expect primary union. The cyst will not recur after operation. The wound will be dressed with a little iodoform-collodion, after having made it perfectly dry with antiseptic gauze.

RACHITIS, GENU VALGUM.

The next case I present to you is a child, two years and six months old. In a case of rickets we generally expect delayed dentition. We have here a case of genu valgum, and it probably depends upon the general condition of rachitis. The chest-walls have in some way had their nutrition interfered with and are misshapen. It appears from the history of the case that the child had a febrile attack last winter. Now, the genu valgum in this case depends on two things: first, weakness of the tibia, and second, failure of growth of the external condyle of the femur. The internal condyle is distinctly longer than the external in this case, hence the operation proposed has been that of chiselling apart the longitudinal section of the internal condyle so as to slide the condyle in the direction of the incision, and thus straighten the joint. A linear osteotomy, or section of the femur just above the condyles, is a favorite operation for this condition. Remember that the tibia itself is perfectly straight in the majority of these cases, and so it is in this case. The tibia and fibula are straight. But there is here a decided lengthening of the internal condyle of the femur, this condyle failing to grow, owing to imperfect nutrition,

and we have the condition you observe. The other leg is straight.

The question of operation is rather a simple one. We divide the femur with a chisel above the condyles; in a short time an abundance of callus is thrown out, which lengthens the bone. I prefer linear osteotomy to the Ogston operation of making a longitudinal section of the femur. The bone can be separated with a few blows of the chisel, the wound united, and covered with iodoform-gauze. The limb is then fixed in proper position with plaster dressing. When recovery takes place the limb will be straight, and the patient be able to walk upon it. There is no chance about this operation, and the only mishap that could happen to the joint would be the non-union of the bone. It is not at all likely in a child of this age, and the ease with which the bone is controlled, as well as the upper shaft of the femur, is such that it is greatly to be preferred to separating the internal condyle.

CONGENITAL TORTICOLLIS.

Here is a case of congenital wry-neck, from shortening of the left sterno-cleido-mastoid muscle. A section would doubtless restore the neck to its normal position, and if there is no paralysis of the opposite side it would be indicated. That it is not due entirely to paralysis is evident from the fact that the head cannot be restored to its normal position without great traction on this muscle. It was probably paralytic in the beginning, but now there is contracture of the tendon. There is a little thickening about the center of the sterno-cleido-mastoid muscle, and doubtless an operation would restore it. (The operation was successfully performed a week later.)

ANKYLOSIS OF THE ELBOW-JOINT, WITH DISLOCATION OF THE RADIUS.

This man has ankylosis of the elbow-joint. He says he received an injury four weeks ago. The power of rotation of the wrist is lost, and there is inability to flex the forearm, and a distinct deformity at the elbow-joint. On examining the ulna, which we can do by tracing its posterior border, beginning with the olecranon, and following it down continuously to the styloid process, there is no break in the line, and no deformity in the ulna. The motion of rotation is mostly performed by the supinators and the pronators of the forearm, the supinator longus and brevis, and the pronator radii teres and the pronator quadratus. The principal action is upon the radius, the ulna being used as a fixed point, around which the radius revolves. The radius must be the bone involved. If it were a fracture, we should have some sign of callus, but there is none such here, except a thickening at the elbow-joint. You will notice how much wider the left elbow is than the right elbow. The injury therefore must have been at that point. My fingers rest on the condyles of the humerus, and the injury therefore has been to the condyles of the humerus, not to the bones of the forearm. We will further trace the humerus and the attachment of the triceps. Taking the olecranon as the starting-point, I grasp the humerus upon the sides, and I find a thickening. The injury has been to the condyles of the humerus, probably a fracture above the condyles, and splitting. At the same time there has been that curious condition which has so frequently failed to be diagnosticated at the time of the injury—*i. e.*, dislocation of the head of the radius—a condition that gives surgeons more trouble than any other form of injury about the elbow-joint. Very often I have seen elbows like this, when a fracture had been properly diagnosticated and set, but at the same time the dislocation of the head of the radius entirely escaped notice. We know the radius is dislocated, because we can trace the bone to a point anterior to the joint. We commence at the lower border of the radius, just as we did with the ulna, trace it directly upward, and we find it rests anteriorly to the joint. By means of a pair of calipers we can measure the difference in these two joints. I place my thumb on the head of the radius and a finger on the olecranon, and you see the difference is very marked. The head of the radius is out of place. To demonstrate this, I place my thumb on the projecting part, and then rotate the wrist. The bone rotates under my thumb. There is now no relief for this condition, except cutting out of the head of the radius. The only time to reduce it was immediately after the accident. I shall operate on a patient at the Marine Hospital for the same condition in a few days, but it has existed for a much longer period. The condition is one of permanence; it will last this man through life, as it is impossible to reduce it at this time, on account of the thickening that has gone on; an exudate has been thrown out, and there has been consolidation of it. There is contracture of the tissues about it. I advise this patient to submit to excision of the head of the radius.

CLINICAL MEMORANDA.

TWO CASES OF CONGENITAL HYPERTROPHY OF THE FINGERS.[1]

BY THOMAS S. K. MORTON, M.D.,
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC; OUT-PATIENT SURGEON TO THE PENNSYLVANIA HOSPITAL; ASSISTANT SURGEON TO THE ORTHOPEDIC HOSPITAL.

CONGENITAL hypertrophy of the fingers or toes is stated by Bradford and Lovett[2] to be "a condition which is occasionally encountered, but which is decidedly rare. It is, perhaps, noted at birth that one digit is larger than the rest, and with the growth of the hand, this abnormally large finger remains proportionately the same, growing more rapidly than the other fingers. It is a hyperplasia of all the structures, although sometimes more marked in the muscular and areolar tissues than in the others. The arteries going to these fingers are larger and the temperature higher than in the normal fingers."

CASE I.—Gertrude P., aged eighteen months, came under observation February 24, 1893. The family history was excellent excepting that a first cousin, a female on the paternal side, had webbed fingers of one hand.

This child was born with the index and middle fingers of the right hand distinctly larger than those of the opposite hand. During the first year of life these fingers did not appear to increase in size much more rapidly in proportion than did their fellows; but during the past

[1] Read before the Orthopedic Section of the College of Physicians, Philadelphia, January 19, 1894.

[2] Orthopedic Surgery, p. 532.

six months the rate of growth in the diseased digits has received great impetus. The mother states that the increase during this latter period has been both actually and relatively very great as compared with the preceding six months. An interesting possibility of maternal impression is connected with the history of this case. When two months pregnant of the child under consideration, the mother was sitting in a street-car holding the index and middle fingers of the right hand within the grasp of all the fingers of the left. Some accident happening to the horses, she squeezed the two fingers of the right hand immoderately for some minutes with the left hand. For some time afterward the squeezed fingers were more or less palsied and the seat of much pain. From that time she was fearful that she had in some manner injured the child, and although she had not distinctly announced her belief that the corresponding fingers of the child would be the seat of defect, yet she was certain that some harm had come to the embryo.

Case I.

Case II.

Excepting the diseased fingers the child is absolutely healthy and well developed in every respect. The overgrowth begins immediately beneath the metacarpo-phalangeal joints, these being practically normal. The bony phalanges are hypertrophied. The interdigital joints are loose and permit of some lateral motion. Flexion for more than one-half of the normal extent is impossible. The terminal phalanx of each affected finger is especially prone to excessive extension. The articulating surfaces of the inter-phalangeal joints, as well as the ligaments, are evidently defectively evolved. Power of movement in the fingers is limited. Flexion is very weak, but extension is comparatively strong. Voluntary lateral movement of the digits is practically absent.

The tissues present a swollen and edematous appearance of hypertrophy, although no pitting takes place upon pressure being exerted. To the touch these tissues feel similar to the overgrowth of skin and cellular substance produced by long-continued congestion of a part. The skin is thin and mottled red, especially upon the flexor surfaces. Sensation appears to be normal. A thick web connects the two diseased fingers as far forward as the second inter-phalangeal articulations. The following comparative measurements were taken: Length of right index finger from metacarpo-phalangeal joint downward, 2¼ inches; of the left, 1½ inches. Right middle finger, 2½ inches; left, 1¾ inches. Circumference at second joint of right index, 2¼ inches; at same point of left index, 1¼ inches; same point on right middle finger, 2½ inches; left, 1¼ inches. The nails of these fingers are enlarged proportionately to the size of the digits, but have a defective, unfinished appearance.

The child had been treated at various times by elastic compression, liniments, sorbefacients, and other measures, without the slightest benefit.

Amputation presenting the only hope of relief, I accordingly removed the fingers at the metacarpo-phalangeal articulation by antero-posterior flaps. A large pad of fibro-fatty tissue was also dissected out from the palm. The parts were exceedingly vascular and a number of catgut ligatures were required. A continuous silk suture, dressing, and splint completed the procedure. Primary union throughout resulted in a very few days. At last accounts the whole remaining portion of the hand was in normal condition.

A dissection of the removed members showed that hypertrophy and degeneration were present in all of the structures of the fingers, and a microscopic examination made by Dr. Charles W. Burr demonstrated that

this hypertrophy was due to a tremendous increase of the adipose and connective tissue.

CASE II.—The child, Martha E. S., is twenty-two months of age. There is no history of a maternal impression, and the family history is negative. Several other children are normal. This child was born by breech-presentation and was almost asphyxiated by the cord being wound around the neck. There was a deep and well-defined groove encircling the left forearm below the elbow, which has grown more shallow, but still is quite prominent and well defined. Below this, great lividity of the forearm and hand persisted for some weeks after birth, but is now confined to the fingers and back of the hand. The arm below the groove was studded with very hard nodules, varying in size from a pea to a small egg. These at first appeared to be attached to the bones, but at the end of a year had all become freely movable. One large hard nodule was also present above the elbow and attached to the humerus. This has entirely disappeared. The condition of all of the affected parts has been slowly improving and at the time of my examination only the fingers and metacarpophalangeal regions are affected with lividity and hypertrophic nodules. There is also a condition of cavernous angioma affecting the fingers and thumb in spots, while in some places dark blood balloons out the thinned integument. Motion and sensation are perfect throughout. The bones, joints, and muscles are unaffected; the skin, subcutaneous vessels, and adipose connective tissue alone being diseased. The palm also is unaffected.

Under elastic pressure and constant application of 10 per cent. of ichthyol in lanolin, marked improvement has taken place in six months and ultimate disappearance of the hypertrophic nodules appears probable. The cutaneous circulation has also markedly improved and the angiomatous condition is disappearing. The groove upon the forearm is likewise growing smaller.

CONGENITAL HYPERTROPHY OF THE FOOT.

BY GEO. ERETY SHOEMAKER, M.D.,
VISITING SURGEON TO METHODIST HOSPITAL, PHILADELPHIA.

A DIAGNOSIS of congenital hypertrophy must not be lightly made. In some cases atrophy of other parts may cause a simulated hypertrophy of corresponding structures. This is particularly true in hemiatrophy affecting one-half of the face or of the body. Cases of this condition have been reported by Osler, Bradford, Stanley Boyd, C. H. Golding-Bird, and others. It is no doubt of central origin, and may be analogous to infantile paralysis, as suggested by Golding-Bird.[1]

Hypertrophy of a part of the face does occur, however. Stanley Boyd[2] reports a case of enlargement of the left half of the face below the zygoma, including the tongue and the inferior maxilla. D. W. Montgomery[3] also reports a case of hypertrophy of the left side of the face.

Pseudo-hypertrophic paralysis can usually be recognized with accuracy. It is a primary disease of muscle, and, while it may be congenital, it follows a definite course, and is accompanied or followed by a definite weakness or paralysis. Akromegaly is a general disease, not congenital, developing usually in adolescence, and slowly progressive. It involves several portions of the body at the same time, as the hands, head, feet, tongue, lower jaw, or thorax. There is said to be invariably a spinal curvature.

Angiose enlargements should be possible of discrimination by touch and general appearance, including color and the presence of enlarged vessels. Myxedema is a disorder that is limited to soft tissues, and is usually progressive.

Various arthropathies of central origin must be excluded. There is also a rare form of hypertrophic osteoarthritis which develops in connection with certain pulmonary conditions, such as empyema.

A number of diseases of the skin are classed as hypertrophies by dermatologists, such as ichthyosis and

elephantiasis Arabum. Among these, sclerema neonatorum is one that in the infant might give rise to confusion. It is described by Duhring as appearing usually at birth, and consisting of a diffused stiffness and hardness of the cutaneous and subcutaneous tissues, accompanied by coldness, edema, swelling, discoloration, lividity, and general circulatory disturbance. It is usually fatal.

In regard to the surgical treatment of true hypertrophies, little need be said. The tissue is often of such a character as not to lend itself readily to plastic work, owing to deficient nerve-supply and blood-supply. Frequently but little can be done, owing to the diffuse nature of the enlargement. Those progressive diseases that are of central origin are not amenable to operative treatment.

The case herewith reported is that of a girl, aged nineteen, from a mountainous region in this State, one of fourteen children, of whom one had a supernumerary thumb, this being the only significant point of family history

[3] MEDICAL NEWS, July 15, 1893, p. 61.

obtainable. She has a history of frequent attacks, apparently of hystero-epilepsy, during the past three years, not directly connected with menstruation. This function, however, has been very irregular for the same period, dating from a severe illness of nearly four months, attributed to overeating ice-cream during the flow. Dysmenorrhea is severe, the pain preceding the flow. The patient has hypermetropia and an internal strabismus of the right eye. Few individuals would appeal to so many specialties in medicine.

The deformity, which was noticed immediately after her birth, affected the outer portion of the left foot, as seen in the accompanying photograph, which shows both feet. The girl was large and well formed, with a well-developed muscular system. The only asymmetry above the ankle, beside the strabismus referred to, was in the calves of the legs, the left being ¾ inch larger in girth than the right. This is a true asymmetry, for the right calf is usually larger than the left in right-handed persons. Owing to the marked dysmenorrhea and the possible relation of the epileptoid convulsions to pelvic disease, a thorough examination was considered justifiable, and was made during the anesthesia induced for the operation on the foot. The uterus was small, almost infantile, measuring 1½ inches. There was no ovarian or tubal abnormality. A firm band of connective tissue, ¼ inch wide, crossed the vestibule from a point immediately behind the urethral orifice to the posterior vaginal wall, somewhat to the right of the median line. It appeared to lie behind the hymen.

The deformity of the foot, as will be seen in the photograph, began just below the external malleolus and involved bone, muscle, and skin. The three outer toes were affected, together with their metatarsals, the outer three-fifths of the sole of the foot, and a corresponding portion of its dorsum. Aided by a firm pad, covered with callus, on the sole, the thickness of the foot was increased nearly three times; the length was increased about one inch by the hypertrophy of the outer toes, while the great toe and the second were normal, as were all the corresponding structures on the inside of the foot.

The skin gradually changed from the normal upon the dorsum over the second metatarsal to dense, hard, immovable tissue over the toes and the outer edge of the foot. It was normal in color and smooth, except for the thick callus upon the sole. The toes were particularly hard and inelastic, and it was evident that the tissues underlying the skin were very hard also, and that the disease was not simply a skin-lesion. Inspection and palpation excluded an angiose enlargement; a true scleroderma is an atrophy and not a hypertrophy. Elephantiasis was out of the question. Dr. Milton B. Hartzell kindly saw the case with me. Having carefully excluded akromegaly, or other disease of nervous origin, and the opinion that it was a simple hypertrophy being confirmed on consultation with Dr. J. H. Lloyd, it was determined to retrench the foot.

The girl was obliged to work for her living, and it was not thought wise, for appearance' sake, to weaken the foot by removal of metatarsals or other essential structures, particularly as there was some risk in obtaining a good operative result.

It would have been impossible to operate through sound tissue and secure good flaps without removing all of the distal half of the foot except the great toe. The vitality of the tissues was considered very low, and the result vindicated the opinion. The two outer toes were therefore amputated where they joined the metatarsals, and the third toe in its continuity. An incision along the outer edge of the foot enabled a large flap to be laid off the sole, when all the hypertrophied subcutaneous connective tissue was removed which it was considered safe to disturb without endangering the plantar flap. The skin appeared to be about one-half an inch in thickness and extremely tough. The muscular tissue exposed was pale and rather soft. The abductor minimi digiti and the short flexor were much enlarged, and were removed in great part. The outer metatarsal was distinctly enlarged. All vessels were tied with catgut. The parts, particularly the skin, did not appear to have even a normal vascular supply, yet the general oozing, though slight, was continuous. This was due to the great hardness of the flaps, which prevented the usual contraction of the capillaries and the shrinking of the tissue under hot water. This oozing continued for ten days, filling the wound-cavity and soiling several dressings. Fortunately the wound remained aseptic throughout its course, and free drainage was provided; but about half an inch of the edge of the upper flap slowly separated by a sort of dry gangrene, requiring several weeks in the process. It was meanwhile a source of congratulation that no essential portions of the foot were uncovered, as might have been the case had a more radical excision been performed.

The final result was excellent. Though still somewhat broader than the other foot, the great improvement was very satisfactory to the patient, who writes, after the lapse of several months, that further shrinkage has taken place. The nervous condition present was of much interest, and received careful study by Dr. Lloyd. The convulsions were general, with well-marked opisthotonos. After the foot had healed these convulsions increased in frequency, twenty or more occurring every day, so that the general health suffered. It is of some interest to recall that there were several other hysteric cases in the same ward, so that it became necessary to isolate the girl. As has been said, these attacks had occurred for several years previously.

While under the anesthetic rapid dilatation of the cervix was performed, with the hope of stimulating the nutrition of the infantile uterus and of possibly favorably affecting the dysmenorrhea. Apparently this was not accomplished while the case remained under observation. No further gynecologic treatment was considered wise.

An interesting point is the situation of the hypertrophy on the outer border of the foot. Charcot has called attention to the fact that it is the little-finger side of the hand that is usually involved in such processes in the upper extremity, and the analogy is followed in this case.

MEDICAL PROGRESS.

The Conduct of Ordinary Labor through External Examinations Solely.—Leopold and Spörlin (*Archiv f. Gynäkologie*, B. xlv, H. 2, p. 337) make a warm plea for limiting examinations made in the course of ordinary

labor to the external parts, and adduce the advantages of such a course. Infection is thereby avoided; the natural sense of modesty of the parturient is not offended; and careless rupture of the membranes is avoided. Skill in external examination is acquired with reasonable readiness. In the large majority of cases such examination alone is sufficient for the recognition of the position and presentation of the fetus, and for the study of the course of an ordinary labor. As there can be no objection to its frequent exercise, abnormalities of parturition may the more readily be detected early, and means of correction promptly employed. Experience soon teaches the difference in the position of the fetus assumed in case of pelvic contraction on the part of the mother. The position and presentation having been recognized by external examination, internal examination for the determination of possible pathologic conditions of the birth-canal need be but brief, and can be conducted with great care. For the attainment of this desirable result it is essential that the obstetric pupil familiarize himself thoroughly with the conditions of normal labor as determined by physical external examination, as well as with the physiology of normal labor. Obstetric operations are principally to be taught upon the phantom.

The Effects of Ligature of the Coronary Arteries.—MICHAELIS (*Zeitschr. für klin. Med.*, B. xxiv, H. 3, 4, p. 270) has confirmed the observation that ligature of the coronary arteries of the dog is as a rule followed in the course of two minutes by irreparable cessation of the action of the heart. The loss of blood or the reduction of temperature consequent upon the operation does not suffice to bring about this result; but these, on the contrary, render the animal the more resistant and defer the cessation of cardiac action. There is a difference in reaction to ligature of the coronary arteries between rabbits and dogs; in the former *restitutio ad integrum* may be brought about after the heart has ceased beating by massage of the heart, while in the latter this seems impossible. The coronary arteries of the dog anastomose with one another. The explanation of the much slighter influence exercised upon the action of the heart by complete ligature of the veins (in the sequence of which irregularity of cardiac action does not appear before an hour), as compared with the effects of ligature of the arteries, is to be found in the considerable flow of venous blood through the foramina Thebesii directly into the cavities of the heart and the consequent entrance of fresh blood through the coronary arteries. Ligature of the coronary arteries is followed by pulmonary edema.

Seborrheic Eczema is discussed fully in a recent monograph by UNNA (*Sammlung klinischer Vorträge*, New Series, No. 79, Leipzig, 1893), who was the first to direct special attention to its peculiarities five or six years ago. The affection is characterized by (1) parakeratosis of epidermis; (2) epithelial proliferation; (3) inflammation of the corium, variable as to depth; (4) augmentation of the fatty secretion of the skin, together with increased activity of the sweat-glands. The disease is microbic in origin, and Unna believes that he has defined two species of organisms, the flask-bacilli (Malassez's spores) and the morococci (mulberry cocci), the former being found chiefly in the crusts and scales of the scalp, the latter in the scales of the body, especially if moist. [Seborrhœa oleosa is regarded by Unna as being due to an affection of the sweat-glands or coil-glands, and as being therefore really a hyperidrosis.] In typical cases the scalp is first attacked, the disease usually occurring between the ages of twenty and thirty. When the hairless regions are involved the diagnosis is not so easy, but the sternal region and the back between the scapulæ are favorite localities. Cleansing the patches with spirit of soap, and the use of ointments of sulphur, constitute the best remedies and are generally effective in curing the disease, though relapses are common.

Allocheiria in the Sequence of Diphtheria.—GAY (*Brain*, part lxiii, p. 431) has reported the case of a girl, thirteen years old, in which four or five weeks after the onset of an aggravated attack of diphtheria fluid regurgitated through the nose, and the voice was extremely shrill and almost reduced to a whisper. Near vision became deranged and diplopia supervened. The pupils were dilated, and reacted feebly to light and in accommodation. The internal recti were paretic. There was no actual paralysis, but a generally distributed weakness. The gait was faltering; station was unsteady; knee-jerks, elbow-jerks, and chin-jerk, as well as the cutaneous reflexes, were abolished. There was considerable ataxia in all four extremities. The sense of hearing, and probably also that of taste, was preserved, but the sense of smell was lost. Slight touches were not perceived, but firmer ones were referred to exactly corresponding points on the opposite side of the body. There was no delay in the transmission of sensory impulses and no polyesthesia or paresthesia. Heat was well discriminated from cold, but the muscular sense was lost in all four extremities. The soft palate was only slightly paretic, but a laryngoscopic examination could not be made. The symptoms gradually ameliorated, and the child was in a little while on the way to recovery.

THERAPEUTIC NOTES.

Salicylated Collodion for Lupus.—SYMPSON (*Practitioner*, No. 308, p. 96) reports the successful employment of the following formula in the topical treatment of lupus vulgaris affecting the skin:

R.—Acid. salicylic. . . . . 5j.
Ext. cannabis indicæ . . . gr. x.
Collodii flexilis . . . ad 5j.—M.
Fiat pigmentum.
S.—Apply topically.

Ammonium Bromid for Tetanus.—NATH (*Indian Medical Record*, vol. vi, No. 2, p. 47) has reported three cases of tetanus treated successfully by the administration of 20 grains of ammonium bromid thrice daily. Two of the patients were kept in a dark room during the progress of the treatment. In one case the condition arose in the sequence of injuries received from the bursting of a gun; in another following an axe-wound; and in the third after a crushing wound by a falling building.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SATURDAY, MARCH 17, 1894.

CARE OF THE INSANE.

In 1869, the Legislature of Pennsylvania created the Board of Public Charities, consisting of five members, and intrusted it with general visitorial powers. In 1883, there was additional legislation, and an act was passed "Relative to the supervision and control of hospitals or houses in which the insane are placed for treatment or detention," which provided for an addition of three members to the Board, which was further authorized to appoint from its own number a committee of five to act as the "Committee on Lunacy." As we understand the law, while large powers are conferred upon the Lunacy Committee it does not possess complete autonomy, and this may have been purposely withheld. The law of 1883 has now been in operation ten years, and through the medium of its annual reports its work is well known. Of this it may be said at once that what has been accomplished is, on the whole, most gratifying. Some of the results and tendencies of the operation of this law, and other legislation relative to the care of the insane enacted the same year, deserve notice at this time.

Aided by the provisions of the new law, and encouraged by a favorable public sentiment, efforts were begun soon after the organization of the Lunacy Committee to transfer the insane poor from the county almshouses to the State hospitals—in other words, to substitute State care for almshouse care of the insane. There was general acquiescence in the proposition to place the insane poor under State supervision. In September, 1892, excluding the counties of Philadelphia, Allegheny, Lancaster, and Lackawanna, which have organized institutions, there were only 250 insane persons remaining in sixty-four counties. It is creditable and remarkable that the change in the State policy has been made so expeditiously and with so little friction.

There does not seem to have been adequate preparation for the reception into the State hospitals of the large number transferred from the almshouses, in addition to the admission of new cases constantly developing throughout the State, and in the execution of the law one result was soon manifest, viz., the overcrowding of the hospitals beyond their intended capacity, and the refusal to admit fresh cases. The story of overcrowding comes from every one of these institutions, and it is easy to read between the lines of their annual reports that their operations as medical institutions are seriously impaired, if not paralyzed, from this cause alone.

In 1891, the Legislature, "at the suggestion of the Board of State Charities," authorized the Board to transfer, in its discretion, patients from the hospitals back again to the almshouses. The same year the Governor vetoed a bill to return the insane to the almshouses and appropriating money for their support therein. Among other things, Governor Pattison said: "I am satisfied the bill is a step backward, and I am not willing to reverse the progressive and humane policy of this Commonwealth by its approval."

It is stated that eighty have been recently transferred from the Harrisburg Hospital to county almshouses in accordance with an order of the Board of State Charities. This movement deserves a notice from the medical press and suggests the question whether these transferred patients go to almshouses any better equipped for their care than formerly. Also, does it foreshadow a return to a system which has been condemned by the humane sentiment of the people and by the Executive of the Commonwealth? If it is the beginning of a reactionary movement, then the medical profession should protest, and urge and strengthen the State Board in its efforts for measures for a continuing elevation of the standard of care for the insane of all classes, rather than by silence seeming to assent to a retrograde

movement which may reverse the policy of State care. Public and professional sentiment will hardly approve of a system which permits dangerous overcrowding of the hospitals, to the embarrassment and detriment of all medical management, and permits the incurable, the chronic, and the helpless cases to drift into the almshouses.

It may be an opportune occasion also to question the wisdom of a system that crowds the insane of all classes—the recent cases, the incurables, and dements of every social condition—into the same wards. The State hospitals must make provision for all of these classes, but facilities for classification may be much improved. There must come in the future the hospital department proper, where the small percentage of the total hospital population who are probably curable may receive the best hospital treatment, and all that it implies, without stint. There will be needed outlying blocks and supplemental buildings for chronic cases. There will be needed also infirmary wards for dements, feeble persons, and paralytics. The whole scheme should be elastic and comprehensive, so as to include the requirements of every class.

Notwithstanding all that has been done, hospital plans are still unsettled, and, as is well known by those who note the tendency of medical thought, are in course of evolution. In this connection, we take this occasion to call the attention of our readers to a most suggestive paper on hospital plans by Dr. Andrew MacFarlane, which appeared in the *Popular Science Monthly*, for October, 1893. We have also called attention to certain distinct reforms advocated by Dr. Stephen Smith, of New York.

THE PATHOLOGY OF LITHEMIA.

In a lecture recently delivered,[1] Prof. Da Costa gave a very lucid exposition of his views of the pathology of lithemia, and, taking these for a foundation, he indicated a line of treatment which certainly appears to be an eminently rational one.

The term "lithemia," as applied to a morbid state, involves much more than the presence in the blood of a mere excess of lithic or uric acid. Hence the proposition of the late Prof. Austin Flint to substitute for the older term the new one, "uricemia," or, even still worse, "uricacidemia," is to be condemned, as it implies that the efficient cause of the symptoms, as well as the leading indication for treatment, is to be found in the abnormal accumulation, or excessive production, of a single excrementitious element. Lithemia is a modified form of gout, and it is the form in which gout particularly manifests itself in this country. It is, in fact, "American gout."

Habitual indulgence to excess, especially in albuminoid food and alcoholic drinks, is manifestly the direct cause both of gout and lithemia. As every lithemic will testify, sugar is especially injurious; so also are all articles of food that are easily made to undergo the acid fermentation, as fermentative dyspepsia aggravates all the symptoms. Lithemia, then, is a morbid state in which the income of nutriment is in excess of the outgo of waste. The quantity of food is greater than either the needs of the system require or the organs of excretion can promptly dispose of. There is defective oxidation as well as deficient elimination. One consequence of the excessive ingestion of food is that the functions of the liver are imperfectly performed, and there is, generally, more or less hepatic disorder. The blood contains urates in excess, and frequently oxalates, also other imperfectly elaborated products of waste; possibly it may be yet further poisoned by ptomaïns resulting from imperfect gastric and intestinal digestion.

The urine of lithemia is, as a rule, dense, high-colored, and of higher specific gravity than normal urine; but spontaneous deposits of urates and uric acid are seldom observed. Small quantities of albumin may sometimes be found; even tube-casts, both hyaline and epithelial, may be discovered; but usually these are transitory and do not indicate permanent kidney disease.

Another point of difference between lithemia and gout is the clinical fact that in the former deposits of urates in the vicinity of joints are not observed, and attacks of acute arthritis of toes or fingers do not occur. There may be, however, a painless enlargement of the terminal finger-joints, especially in elderly people, with impairment of function. The cardiac hypertrophy and kidney-degeneration of true gout do not belong to the clinical history of lithemia. The blood-tension may be increased, but it is so to a less degree than in gout, and the arteries do not exhibit the atheromatous condition that characterizes the graver form of disorder.

As the organic lesions are slight, the prognosis

[1] Lecture delivered by invitation before the medical classes, in the Medical Hall of the University of Pennsylvania, March 6, 1894.

is correspondingly favorable, provided the symptoms are properly interpreted and a rational treatment is instituted.

The symptoms of lithemia have been so well described by the same skilled hand, in previous contributions to the literature of this very interesting form of disease, that they should be familiar to all. There is the impaired digestion, the muscular pains, the neuralgic attacks, and pains in the tendons (notably in the tendo Achillis), the indisposition to exertion, the lack of ambition, the irritability of temper, the depression of spirits, and the general gloom, the frequent and severe attacks of vertigo and of migraine, the restlessness, with jerking muscles, at night, and the drowsiness during the day—all of which combine to make the life of the poor lithemic far from a happy one.

The tendency to lithemia may be acquired in the manner already sufficiently indicated, or it may be inherited from gouty or over-fed ancestors.

The suggestion of Dr. Wm. Roberts regarding the formation, under such circumstances, of the less soluble biurates in place of the more soluble normal quadriurates, is a plausible and probably the true explanation of the phenomena of gout; but, like Haig's uric-acid theory, it is too restricted and does not sufficiently account for the phenomena of lithemia. A neuro-humoral hypothesis similar to that proposed for gout by Sydenham appears, on the whole, to be more in accord wth the facts, the lithemic condition being due to faulty metabolism as well as to poisoned blood.

Keeping in view the pathology of lithemia as outlined, we are prepared for the statement that the most important factor in the treatment is the regulation of the diet. The food need not be strictly vegetable, but the nearer it approaches this standard, the better for the patient. Green vegetables (except asparagus), fresh fruits, stale or toasted bread, with the white meat of poultry and fish, should constitute the main reliance. An excess of carbohydrates, especially sugars, should be avoided. The only drink allowed should be water, which should be taken in sufficient quantities to keep the kidneys active. Mineral waters may be ordered to accomplish the same purpose. Alcohol should be positively excluded, except that elderly patients, who have been all their lives accustomed to the use of stimulants, may have whiskey or a good, sound claret with their meals. Exercise in the open air is also an important part of the treatment. As regards the purely medical management of the lithemic state, too much physic is to be avoided. Saline laxatives are very useful. A combination of lithium carbonate (gr. ij.) with extract of nux vomica (gr. $\frac{1}{6}$) given after meals is of special value. In attacks of lithemic migraine, a few doses of a mineral acid, it is claimed, will often cause the symptoms to disappear. An important point of treatment is to watch the digestive organs and scrupulously avoid food that causes fermentation, with the consequent production of an excess of acid in the stomach.

THE STUDY OF IDIOCY AT ELWYN.

It has long been recognized by a few specialists in this city that the opportunities for the scientific study of idiocy at the Pennsylvania Training-school for Feeble-minded Children, at Elwyn, were unparalleled in this country, and perhaps not excelled in the world. It has been equally recognized that these opportunities have not been utilized in the past as thoroughly and systematically as could have been wished. It is not necessary or pertinent to enter now into a discussion of any possible causes that may have conduced to this. The labor of organization in a comparatively new and rapidly-growing institution, and the ever-present duties of administration, seemed in this, as in so many of our American asylums, to rise up, like Jonah's gourd, and spread out and obscure all the other interests. The scientific work at best was sporadic, and while it was excellent in its way, it was confined rather too exclusively to desultory papers and to annual reports. The fact that the most notable scientific production of the institution in all its history was the work of an outsider suggested, to some minds at least, that the opportunity to do such work ought to be offered more liberally to scientists who were not directly connected with the school, and who could bring to its service from beyond its own walls the skill and attainment of trained experts in both pathology and clinical medicine. Whatever obstacles existed to such a plan seem in the course of time to have been eliminated, for at their recent meeting the Board of Directors, with a liberal and enlightened policy fully abreast of the spirit of the time, appointed a full staff of neurologists, physicians, surgeons, and specialists to take up the scientific work. It is thoroughly understood by both the Directors and the members of the new staff that the duties of the latter are in no sense to be merely perfunctory, but that these consultants are not only to

participate in but also to lead and direct the practice and the researches undertaken in the school.

We think that this ought to inaugurate a new era in the study of the pathology and treatment of idiocy in this city. That this great institution, lying almost within the suburbs of Philadelphia, and ministering to the wants of almost one thousand feeble-minded children, should have contributed from out its rich storehouse so little to the advancement of science and to the reputation of this great medical center is an anomaly that we trust will not continue longer to be seen. With less material and opportunity the reputation of some European schools has been made; from little if any greater field BOURNEVILLE has contributed his annual volumes to the elucidation of this most important specialty. The necessity for a too exclusive attention to the labor of organization no longer exists to the same degree as formerly, and can be met by the Board to whom it properly belongs, while the details of administration will be wisely distributed among officials who are not responsible for the scientific work.

The subject of idiocy still offers many problems of the first importance both to the pathologist and to the sociologist. The prevention and treatment of feeble-mindedness can never be thoroughly established until the pathologist masters the subject more thoroughly than at present. The relations of idiocy to heredity, to the various dyscrasiæ and toxemiæ, to the complications and accidents of childbirth, and to the infectious processes, are a few only of these problems. While to the humanitarian the care and education of the imbecile brain may seem to be the prime object, to the sociologist the regulation and control of those evil forces conducing to the production of this sad social blight will ever be paramount. These varied and far-reaching problems, social, humanitarian, and scientific, all come to a focus in such an institution as that at Elwyn. It is hoped and believed that the liberal policy now inaugurated by the Board of Directors will be justified by the fruits of a wise and thorough scheme of scientific work.

EXTIRPATION OF THE LARYNX.

EXCISION of the larynx is not being practised as frequently as it was a few years ago. One or more operators of large experience have expressed themselves in its disfavor, arguing that the disappointments in regard to the safety from recurrences of malignant disease in the tissues whence the extirpation has been made, and the short average of life thereafter, do not justify the risks taken in submitting to the excision.

On the other hand, a few exceptional cases have recently been reported in which the immediate and prospective success has been unusually favorable. In these cases attempts have been made to avoid the danger of escape of food, saliva, mucus, and débris into the air-passages, by the device of stitching the orifice of the severed trachea to the skin in such manner as to cut off all communication with the wounded tissues.

More than this has been accomplished; for by stitching the trachea in this way a large permanent orifice is obtained, so that a tracheotomy-tube or other canula is dispensed with; and thus a serious source of irritation is circumvented, *i. e.*, irritation due to the presence of a foreign body in the wound. The recoveries from operation have been more prompt than formerly, and the periods at which food could be taken in the ordinary manner much earlier. Indeed one case at least is on record in which food was satisfactorily swallowed immediately after the operation.

Furthermore, in some of these cases there has been no attempt to substitute an artificial larynx for the organic one, and yet attempts to speak with the structures as they have been left or have become modified during cicatrization have culminated in the production of voice far superior to that produced by an artificial appliance.

May it not be that the withholding of foreign bodies from the wound will render excision of the larynx more encouraging in the near future?

EDITORIAL COMMENTS.

The Retort Courteous.—In the *Journal of the American Medical Association* for March 10, 1894, occurs the following editorial utterance:

"CAPTIOUS CRITICS.—We are naturally pleased to see the great interest taken in the articles from time to time published in the *Journal*, but when the editors of other journals pervert friendly interest to carping criticism on what we do *not* publish, we have a clear right to invite their attention to a homely adage which reads, '*Mind your own business.*' It is with sincere regret that we apply the invitation to the editors of the PHILADELPHIA MEDICAL NEWS and the *Pittsburg Medical Review*, but their bad manners in attacking Dr. Woodbridge, a valued contributor, and a worthy member of the Association, for daring to divide his article in two parts; and attacking in savage strain the editor of this *Journal* for presuming to publish the same (also in two parts), seems to show a desire to find fault, as ridiculous as it is senseless."

Our contemporary is as courteous as it is truthful, and as truthful as it is courteous; and we should feel derelict did we fail to acknowledge in a befitting manner its courtesy and its truthfulness. In order to exhibit still more fully the heinousness of our offence and the offence of our always outspoken contemporary of Pittsburg, we must point out a fact or two that have escaped the memory of the *Journal*.

In its issue of February 10th was published a paper entitled "Can Typhoid Fever be Aborted?" read by J. E. Woodbridge, M.D., before the Mississippi Valley Medical Association, October, 1893. This paper claimed that a certain treatment of typhoid fever, original with the author, was infallibly curative, and frequently aborted the disease. We patiently read and re-read every word of the paper to find some intimation of the nature of the treatment, or some promise to publish the treatment later. We searched carefully through the editorial columns of the *Journal*, to find some allusion to this omission, some intimation that it would be rectified. Strange to say, we were unable to find either in the paper or in the editorial columns, what was not there, and our Pittsburg contemporary seems to have been equally unfortunate. Had we been possessed of "second sight," as was clearly our duty, we would have known that the "second part" of a paper apparently finished and read at Indianapolis, Ind., in Oct., 1893, and published on Feb. 10, 1894, was to be read in Mahoning Co., Ohio, on Feb. 12, 1894. We cannot refrain from expressing our admiration of the editorial brilliancy which places as a heading over this "second part" (which, however, the author terms "second paper"), read at a different place and time from the "first part," the words: "Continued from page 187, February 10, 1894." This is a new departure in journalism, as bold as it is unlikely to be imitated.

We are sincerely glad that Dr. Woodbridge, by this second paper, and the *Journal* by its publication, have in so far redeemed their characters. We forbear to comment upon the second paper, believing its peculiarities to be due more to error of judgment than to wrong intent. We are rejoiced to find the *Journal* becoming sensitive to criticism, as this is an indication that it may finally learn that the Association owns the *Journal* and that the *Journal* does not own the Association.

We trust, moreover, that the lesson of the whole "*ridiculus mus*" will not be lost on editors and authors in general. Notwithstanding the apparently condoned aberrations of many men, the profession, as represented by the American Medical Association, is devoted to the principles of right conduct embodied in the Code of Ethics, and no one can long transgress them without being called to account. Even those who succeed in obtaining position and influence while violating the Code, have, after all, but the wirepuller's success; they have neither the esteem, the respect, nor the confidence of those whose good opinion is to be desired.

A Study of Dietaries.—As the mode of life, and particularly the food-supply, of a community has a most important bearing upon general and individual health and length of life, the results of some observations detailed in a study of dietaries recently made under the auspices of the College Settlements Association are of more than ordinary interest. The observations were made partly in Philadelphia and partly in Chicago, and include some fifty individual dietaries. Among other things, the theory that man's natural appetite, when not controlled by extraneous circumstances, leads him to take the food that supplies all the nutritive elements that he needs, and in about the right proportions, was corroborated. In twenty-three dietaries it was found that an average of 21 per cent., by weight, of all the food consumed was bakers' bread, which is usually raised excessively, dries quickly, and lacks nutritive power, so that the diet of a majority of persons in any large city would be improved by providing bakeries where good whole-wheat and white bread could be bought at reasonable prices. To the same end, a taste for good home-made bread should be cultivated to as large an extent as possible. The cost of living is increased among the poor by the necessity of having to purchase the raw materials in small quantities. Besides, however, some of the excess of cost is due to lack of intelligence in purchasing and want of knowledge as to the nutritive values of different articles of food. It is pointed out that by a more general use of peas, beans, cornmeal, and the cheaper cuts of meat, dietaries can be cheapened as to cost, and at the same time increased in nutritive value. It is admitted that to work with individuals to bring about improvements in these respects would be an arduous and lengthy task, and it is believed that the most effective and rapid way to accomplish the desired result of rendering attractive and palatable inexpensive yet nutritious fare for working people, indeed, for all persons, is through kitchens and restaurants, as the New England Kitchen in Boston and the Hull House in Chicago, where such dishes as the best scientific and practical knowledge of the day can produce are served, or sold to be taken home. In connection with such kitchens there might also be lectures on cooking and centers for the sale of raw materials of food of the best quality.

We have before alluded to the noble work done by the College Settlements Association, and the encouragement and aid physicians may give this body in its labor for the hygienic and social progress of the crowded poor of great cities. The Secretary, Mrs. Florence Y. Humphries, 2348 North Twenty-first Street, Philadephia, will answer inquiries and supply literature on request.

Infection through Cigars.—Attention has been directed from various quarters to the possibility of transmitting disease through cigars, which receive a good deal of manipulation in the process of manufacture. It is not uncommon for the unfinished product to be taken into the mouth and a small portion bitten off, while the saliva is often used, applied either directly by the tongue or lips or by a finger. In illustration of this risk we need but refer to a report of two cases of labial chancre in cigar-makers contained in THE NEWS of July 15, 1893, p. 68. It can readily be understood that tuberculosis might likewise be transmitted in the same way. Investigations undertaken by a Roman physician tend to show that this channel of transmitting tuberculosis is restricted by certain limitations. Thus, cigars made in the usual manner, but moistened with saliva known to contain tubercle-bacilli, were by inoculation-experiments found to have lost their infectiveness ten days after

having been dried and packed in the ordinary way. While the risk of infection thus appears to be minimized, it is none the less a real one, and measures restraining the use of the saliva should be rigidly enforced. Further, in the selection of cigar-makers we should consider justifiable a preference for those free from all infectious disease.

Two Portals of Entry for the Tubercle-bacillus.—There are not a few cases of tuberculosis in which the source and route of infection elude detection. Boulland (*Limousan Méd.*, No. 9, p. 129; *Revue de la Tuberculose*, 1893, No. 4, p. 367) calls attention to two possible channels of communication which have hitherto received little or no consideration. The exposed cavity left in the gum after a tooth has fallen out spontaneously or has been removed surgically presents an absorbing surface capable of affording lodgment for tubercle-bacilli that may be present in insufficiently cooked tuberculous meat or other food. Under these circumstances tuberculous involvement of the glands of the neck may be the first indication of infection. The second mode of infection is by the entrance into the ear of the child during labor of blood of the mother containing tubercle-bacilli, with the development subsequently of a tuberculous suppurative otitis, which may in turn lead to general infection. It thus becomes a wise precaution to irrigate with an antiseptic solution the ears of children born of tuberculous mothers.

The Laws of Alabama, as we are informed, protect a physician of that State in his practice and in publishing the following advertisement:

Wanted.—Healthy left male arm from shoulder down; subject must be white and between twenty-five and thirty-five years old; arm to be amputated two inches below shoulder-joint and grafted on another man's body. Will pay handsome price. Apply to the surgeon, Dr. ———, ——— Street, Birmingham, Ala.

The methods of treatment of this individual are thus described:

He cuts two deep incisions in the back for headache, taking a poor man's horse in part of a fee of $200 therefor. He punctures the cornea of an eye that is wholly lost, gouges about in the globe, saying "the sight would be entirely restored by thus stimulating the optic nerve"—for which his charge is $25 in advance. His office is crowded at all times.

Untrustworthy Reports of Medical Facts are the most common things in the daily papers, but when echoed in medical journals severe editorial responsibility should come into play. An instance has lately occurred. Some joking newspaper reporter, finding his "reports" of facts all too small, took it into his head to record the birth of quintuplets at Kittanning, Pa. Our only wonder is that he didn't credit Mrs. Rosenberger with six or eight instead of five children as the result of a single labor. But the quintuplets aroused our suspicion, and we wrote to a reputable physician of Kittanning as regards the truthfulness of the report. He replied that he knew the Rosenberger family well, and that the whole story was absolutely without foundation. The lady had never even borne twins, and no child within the past year. Despite this, medical journals are solemnly repeating the story, and obstetric statistics will be falsified by it to the end of time.

REVIEWS.

The National Dispensatory. Containing the Natural History, Chemisty, Pharmacy, Actions and Uses of Medicines, including those recognized in the Pharmacopeias of the United States, Great Britain and Germany, with numerous references to the French Codex. By Alfred Stillé, M.D., LL.D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania; John M. Maisch, Ph.M., Phar.D., Late Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy, Secretary to the American Pharmaceutical Association; Charles Caspari, Jr., Ph.G., Professor of Pharmacy in the Maryland College of Pharmacy, Baltimore; and Henry C. C. Maisch, Ph.G., Ph.D. New (fifth) edition, thoroughly revised, according to the new United States Pharmacopeia (7th Decennial Revision, 1894). 8vo, pp. 1910, with 320 illustrations. Ready Reference Thumb-letter Index. Philadelphia: Lea Bros. & Co., 1894.

The publishers of this great work may justly pride themselves upon its issuance five months after the publication of the new Pharmacopeia, and but one month after the date assigned for the latter to go into effect. The sweeping changes of the new official standard have been thoroughly incorporated, additions have been made from the latest editions of foreign pharmacopeias, and ample space—in our judgment a little too much space—has been devoted to the new synthetic drugs and unofficial preparations. Many new tables have been introduced from the new Pharmacopeia and elsewhere. Weights and measures are given in both the ordinary and the metric systems, and for the convenience of pharmacists the official formulas have been given in reduced and convenient quantities, according to the customary apothecary's weights and measures. The editors state that in no previous edition have the alterations and additions been so great; that the pharmacists will find a full discussion of chemic and pharmaceutic processes, with descriptions and explanations of the most approved apparatus and tests; that the pharmacopeial formulas for galenic preparations have been freely commented on, and improvements suggested wherever such have seemed desirable. Dr. Stillé has contributed in the preface an appreciative note upon the character of his lamented colleague, Prof. John M. Maisch. The publishers state that prior to the death of Dr. Maisch, the latter had practically completed the portion of the work he had reserved for himself, while the remainder was intrusted by him to Prof. Charles Caspari, Jr., whose name, together with that of Dr. Henry C. C. Maisch, now appears upon the title-page.

The therapeutic portion of the work, that in which our readers will take the greatest interest, remains, as before, under the care of Prof. Stillé, and has been revised with his accustomed thoroughness. Dr. Stillé emphasizes, in his preface, the value of the empiric as contrasted with the dogmatic method of therapeutics,

contending that the practical physician must depend finally upon experience alone. In the Index of Therapeutics, under the name of each disease is a list of all the medicines employed in its treatment, and in the articles relating to each medicine are set forth the conditions calling for the employment of the remedy in question. There can be no doubt that, properly employed, the great mass of empiric knowledge to which attention is thus directed must prove of great service in the management of cases of disease, yet it is obvious that a high degree of critical judgment must be brought to bear in estimating the value of the recommendations of the various observers quoted, and that one may sometimes be confused by the very richness of the material placed before him. For instance, under Leukorrhea we find a list of 113 remedies; for Gravel, 57 drugs are tabulated, and so throughout the list.

It must not be forgotten that on turning to the page upon which the individual remedy is discussed, we find judicial and sometimes caustic criticism of its claims, and thus one can be sure that a statement which receives Dr. Stillé's indorsement is one which he has either practically put to the test, or which commends itself to his judgment by its source and by its accordance with reason and sound principles of medicine.

To point out in detail the merits of this stupendous achievement of science and industry would be an endless task; to state the few deficiencies we have noted is a brief matter. D. D. Stewart's investigations have conclusively proved that the proprietary substance called hydro-naphthol did not deserve any recognition apart from the virtue of the beta-naphthol it might contain, and that the so-called discriminating tests were fallacious. We are therefore sorry to see hydro-naphthol given separate mention and reference to Stewart's work omitted. We cannot agree with the author's somewhat slighting estimate of the value of creosote and of iodoform in the treatment of pulmonary tuberculosis. We have been unable to find reference to one of the best salts of quinin, the double hydrochlorate of quinin and urea, the usefulness of which by hypodermatic injection has been conclusively proved.

Quinin chlor-hydro-sulphate is also omitted. Sodium succinate, which is not mentioned, is a useful remedy in the treatment of biliary lithiasis. While there is a good article on calcium chlorid, one of its most important uses—as a hemostatic and a remedy in hemophilia—is omitted. We must call especial attention to the very just estimate that Dr. Stillé places upon antipyrin and its poisonous congeners, and his implied condemnation of the entire practice of antipyretic medication. It is true that the profession is recovering its sanity on this subject, but Dr. Stillé's weighty words cannot fail to confirm that wholesome tendency.

In conclusion, we must again express our admiration of the manner in which authors and publishers have done their respective shares of the work, and congratulate American science upon having produced a pharmacologic commentary at once so modern in its comprehensiveness and its thoroughness, and so loyal to long-established professional and scientific principles in its inspiration. There is no other guide so safe or so sure.

Pyogenic Infective Diseases of the Brain and Spinal Cord: Meningitis, Abscess of Brain, Infective Sinus-thrombosis. By William Macewen, M.D., Glasgow. 8vo, pp. 354. New York: MacMillan & Co., 1893.

Atlas of Head-sections. Fifty-three Engraved Copper-plates of Frozen Sections of the Head, and Fifty-three Key-plates, with Descriptive Texts. By William Macewen, M.D. 4to. New York: MacMillan & Co., 1893.

Although issued concurrently, these two books have not the relation of text and atlas. Each is complete in itself.

The one first named is a surgical monograph of a very high order. Its keynote is to be found in the preface, where the author states that within the last ten years he has had experience leading him to believe that abscess of the brain and other pyogenic intra-cranial affections are of more frequent occurrence than has been usually supposed, and to take a less somber view than he formerly did of the chances from operative interference in cases of this kind.

The first chapter contains a clear and philosophic exposition of the surgical anatomy of the brain and its coverings, at various periods of life. Especial stress is laid upon the intra-cranial circulation, and upon the arrangement of the veins so as to secure an even, regular, constant flow of the blood, without fluctuation, and free from suction-interference on the part of the large extra-cranial veins. A point of some importance is the description of what the author proposes to call the "supra-meatal triangle of the temporal bone"—a space, usually depressed, just above the meatus externus, and below the posterior root of the zygoma; here access is best gained to the mastoid antrum.

In the second chapter, on pathology, an account is given of the various intra-cranial lesions which may result from pathogenic and saprophytic causes, and of the manner in which microörganisms reach the interior structures. Here, as might be expected, much is said regarding suppurative inflammations, acute and chronic, of the middle ear. The mode of formation of abscess in different portions of the brain is described. Leptomeningitis, in its various forms, and encephalitis, are discussed. A brief section is added upon tuberculosis and carcinoma as met with in the middle ear.

The third chapter deals with the symptoms of cerebral abscess, and the fourth with thrombosis of the intracranial sinuses, in its two recognized forms—marasmic and infective. In these and the preceding chapter, the views advanced are illustrated and enforced by clinical histories, more or less full in detail.

The fifth chapter is devoted to the subject of treatment. Prophylactic measures must be enforced, chiefly in the way of thorough antisepsis and asepsis. In a very large class of cases, for the most part of a kind which at first, at least, are entrusted to specialists in aural surgery, the failure of ordinary means should lead to a resort to operative interference. As to this, the author gives very full and clear directions. For opening the mastoid antrum, he prefers the rotary burr, driven by a surgical engine, to any other instrument. He justly objects to the use of the chisel and mallet for this purpose,

on account of the risk of damage to the contained parts, either from the unavoidable concussion, or from direct wounding, as well as because of the comparative roughness of the opening thus made.

In the sixth chapter we find a statement of the practical results obtained by the author from the carrying out of his views as set forth. These results are very modestly presented, and bear the impress of candor; they certainly afford a very strong warrant for the acceptance of his teachings.

We regret much that the limitations of our space forbid an extended analysis of the material contained in this very important work, but oblige us to be content with the foregoing brief *résumé* of its scope. The history of the recent development of brain-surgery is, indeed, instructive. Perhaps in no other field have greater or truer triumphs been achieved as the result of scientific research, demonstrating the causal relations of morbid processes, rendering operative interference at once rational, effective, and safe, and banishing the so-called conservatism, under which the surgeon sat "letting 'I dare not' wait upon 'I would'" while his patient drifted along to death.

We cannot conclude without referring to the beauty of the illustrations, sixty in number, all but three of which have been prepared expressly for the work before us. They are not only fine artistically, but singularly faithful and suggestive as representations of anatomic or diseased conditions. The typography and mechanical execution of the book leave nothing to be desired.

The other work now under notice is equally deserving of praise. It consists of fifty-three admirably-executed copper-plates, representing sections of the head. Of these, twenty-four are coronal, eleven sagittal, and eighteen horizontal. Each one has opposite to it a key-plate (woodcut) in outline, with a few lines of explanatory text. The coronal sections are in three series, the first consisting of thirteen from a subject sixty years old, the second of seven from a man of forty, and the third of four from a child aged two and a half years.

The eleven sagittal sections are all from the same subject, a man thirty years of age.

Three subjects, males, aged respectively thirty-five, fifty, and five, have supplied material for the horizontal sections: eight being taken from the first, two from the second, and eight from the third.

These plates are very interesting, and by means of them the relation of the various parts of the brain to one another and to the exterior of the skull is clearly shown. They will greatly aid the earnest student of cranial topography, and enable him to profit far more by his practical work in dissection and at the bedside.

Much credit is due the publishers for their enlightened enterprise in giving to the profession these admirable specimens of the book-maker's art.

Lectures on the Surgical Disorders of the Urinary Organs. By Reginald Harrison, F.R.C.S., .etc. Fourth edition, rewritten. 8vo, pp. 588. London; J. & A. Churchill, 1893.

This new edition of Mr. Harrison's well-known work will be cordially welcomed by a large class of readers. Although not a treatise, it contains a vast amount of information, the outcome of a wide and carefully digested experience. The material has been largely recast, with additions embodying the recent advances in genito-urinary surgery. These, indeed, are neither numerous nor important; among them we may note the operation of suture in cases of rupture of the urethra, the suprapubic opening of the bladder, the use of the cystoscope, and the employment of cocain as a local anesthetic in the urethra.

However desirable it may be, theoretically, to secure accurate apposition of the divided ends of a urethra, our own experience has been that the results of free perineal incision and the tying-in of a soft catheter are thoroughly satisfactory to both patient and surgeon. And we should judge that, except in most dextrous hands, the application of sutures would be not only difficult, but likely either to fail altogether or to give rise to stricture of an intractable form.

We are glad to find the suprapubic route to the cavity of the bladder—the simplest, safest in most cases, and in many the most practically useful—favored by so high an authority.

Mr. Harrison's expectations from the cystoscope, we must confess, are more sanguine than our own. We can remember when the instruments of Cruise and Desormeaux excited much enthusiasm among our fellow-surgeons; and while the electric lamp obviates one of the difficulties in their use which led to their abandonment, we have grave doubts as to the value claimed for the newer appliances. That they may, in a limited range of cases and under skilled manipulation, give some information to practised eyes, is very probable. But that the cystoscope will ever become, like the stethoscope, an article of daily use, to be found in the hands of the rank and file of the profession, we can hardly imagine.

In speaking of sounding, Mr. Harrison says that the sensitiveness of the urethra may be lessened "by a preliminary injection of a 10 per cent. solution of cocain." We think it would have been well to state the amount. One dram of a 20 per cent. solution, used in this way, has proved fatal in twenty minutes in a case reported a few years ago; and it is well known that the susceptibility varies in different subjects, so that in some a smaller quantity might be dangerous.

Apart from its great general merit, there is one feature of this book which should commend it to the profession in this country—the author extends thorough recognition to the work of American surgeons.

CORRESPONDENCE.

A CASE OF SCROTAL ERYSIPELAS.

To the Editor of The Medical News,

Sir: I was called to see Mr. N., thirty-seven years of age, on February 16, 1894. I found him suffering severe pain in the perineum. The temperature was normal; the pulse somewhat exaggerated; the tongue not coated. The man explained that he had recently been afflicted with a number of boils, especially one on the perineum, which had apparently healed. He had also ridden on a horse without a saddle, which had injured the boil.

Upon examination I found the perineum and the most dependent part of the scrotum red, swollen, and congested. I ordered flaxseed poultices to be applied to the part during the night and prescribed morphin sulph., gr. ss, to be given at intervals to relieve pain. Next morning at 8 A.M. I found the patient had passed a restless night. The scrotum was more swollen; there was still no abnormality of temperature and no constitutional symptoms, and the appetite was fairly good. The treatment was continued. On the evening of the same day, at 5 P.M., I found the man's temperature 101°, the pulse 90, the tongue slightly coated. I then added quinin sulphate and tr. ferri chloridi to the treatment. On the morning of the third day I found the scrotum very much swollen and painful, *not pitting* on pressure and not itchy. The swelling had extended to the penis, the femoral region, and the inner side of the thighs. The temperature was 104°, the pulse 120, the tongue more coated and dry. I ordered a purgative of magnesium citrate, and directed starch poultices to be applied. On the evening of the third day, at 6 P.M., I found the patient's bowels had moved. I now noticed a small abrasion of the skin near the median line of the scrotum which was discharging a thin watery fluid. On the morning of the fourth day, twelve hours after the last visit, I found the whole of the scrotum black and discharging freely, and a considerable amount of sloughing of the penis. The patient was now lapsing into a comatose condition, and death ended his sufferings at 1 P.M. the following day, February 20th.

Gross's *System of Surgery* speaks of scrotal erysipelas or the inflammatory edema of Robert Liston.

Respectfully yours,

R. Warren Ramsay, M.D.,

Delta, Pa.

GALVANO-PUNCTURE FOR HYPERTROPHIED TONSILS.

To the Editor of The Medical News,

Sir: In the issue of The Medical News of February 17, 1894, Dr. Ward in his article on "New Ideas, etc.," does serious injustice to the results of galvano-puncture in the reduction of hypertrophied tonsils.

He states that "under the most favorable auspices galvano-puncture will require not less than a dozen sittings to produce any decided result." He also says that "it is unnecessary to state that the pain produced by this method of operation offers quite a serious obstacle to its employment."

Both these statements are entirely incorrect. The operation can be made entirely painless by brushing the tonsils with a 20 per cent. cocain solution and by instilling a drop or two of a 4 per cent. cocain solution into each lacuna, the patient being cautioned not to swallow any of the drug.

It need never require more than two sittings (and generally but one) to shrink the largest tonsils to normal size by the following method: The cautery-point is inserted as deeply as it will go into each lacuna, brought to white heat, and withdrawn in a couple of seconds.

After the cauterization of each lacuna, a flat cautery electrode (or the needle electrode curved so as to adapt itself to the tonsil) is passed over the surface of the tonsil and several furrows drawn. There is little or no after-pain. The slough is cast off gradually during the following fortnight, and the tonsil reaches its maximum of shrinkage in about four weeks. A repetition of the painless, bloodless procedure, easily practised on both children and adults, is rarely necessary.

Edwin J. Kuh, M.D.

Chicago, Ill.

A PRACTICAL METHOD OF REGISTRATION OF TUBERCULOSIS.

To the Editor of The Medical News,

Sir: Believing that many physicians are thoroughly in earnest in their efforts to prevent the spread of tuberculosis and to reduce the present high mortality from this disease, I offer the suggestion that some medical society, the County Medical or the Pathological, for instance, establish a private registry wherein may be recorded all such cases of tuberculosis as willing and volunteer members may chance to discover in their private or public practice, so that such particulars as shall relate to the causation, as inheritance, occupation, exposure to infection, hygiene of the individual and of the locality, color, race and nativity, etc., shall be definitely stated, so that a scientific and accurate investigation extending over some period of time might be had. The value of such a registry would appeal to all intelligent physicians, and their active coöperation could probably be obtained. This would in nowise interfere with the liberty of the patient, and must surely prove of incalculable value to the student. The expenses of the undertaking would be nominal.

Very respectfully,

M. V. Ball, M.D.

Philadelphia.

NEWS ITEMS.

American Medical Association.—The Section on Surgery and Anatomy will devote a portion of time to the systematic consideration of a few selected subjects, upon which papers, each not occupying more than ten minutes, will be read. It is hoped that speakers discussing these papers will confine their remarks to brief addresses of five minutes' length. The following papers are announced:

"The Pathology of Malignant Growths," by Dr. E. Laplace, of Philadelphia; "A Critique of the Sporozoan Theory of Malignant Neoplasms from a Micro-technical Standpoint," by Dr. A. P. Ohlmacher, of Chicago; "Clinical Recognition of Malignancy in Tumors," by Dr. C. A. Wheaton, of St. Paul, and Dr. Henry W. Coe, of Portland; "The Necessity of Early Surgical Interference in Malignant Tumors," by Dr. R. A. McLean, of San Francisco; "The Value of Caustics in Malignant Growths," by Dr. John Parmenter, of Buffalo; "The Radical Cure of Malignant Tumors by Operation," by Dr. J. H. Wythe, of Oakland, Cal.; "The Value of Inoculations with Septic or Toxic Agents in the Treatment of Malignant Neoplasms," by Dr. John A. Wyeth, of New York; "Early Symptoms and Diagnosis of Tuberculous Joint-disease," by Dr. Emmet Rixford, of San Francisco, and Dr. A. B. Judson, of New York; "Conservative Treatment of Tuberculous Joints," by Dr. R.

H. Sayre, of New York, Dr. Harry M. Sherman, of San Francisco, and Dr. James E. Thompson, of Galveston; "Operative Treatment of Tuberculous Joints," by Dr. Robert W. Lovett, of Boston; "Treatment of Tuberculous Joints by Injections of Iodoform," by Dr. N. Senn, of Chicago; "Treatment of Tuberculous Joints by Injections of Corrosive Sublimate," by Dr. R. H. Plummer, of San Francisco; "The Causation and Prevention of Hernia," by Dr. James T. Jelks, of Hot Springs, Ark., and Dr. C. M. Richter, of San Francisco; "The Management of Reducible Hernia," by Dr. Emory Lanphear, of Kansas City, Mo., and Dr. C. M. Fenn, of San Diego, Cal.; "The Treatment of Irreducible Hernia," by Dr. James B. Eagleson, of Seattle, Wash.; "The Treatment of Strangulated Hernia," by Dr. Joseph Ransohoff, of Cincinnati; "The Radical Cure of Hernia," by Dr. W. E. S. Davis, of Birmingham, Ala., and Dr. H. O. Marcy, of Boston; "The Pathology and Symptomatology of Hemorrhoids, Anal Fistule, and Anal Fissure," by Dr. J. M. Matthews, of Louisville, and Dr. David Powell, of Marysville, Cal.; "Treatment of Hemorrhoids," by Dr. H. M. Bishop, of Los Angeles, Cal., and Dr. Charles B. Kelsey, of New York; "Treatment of Anal Fistule," by Dr. J. McF. Gaston, of Atlanta, and Dr. G. B. Somers, of San Francisco; "Treatment of Anal Fissure," by Dr. Thomas W. Huntington, of Sacramento, and Dr. Lewis H. Adler, Jr., of Philadelphia; "Treatment of Fractures of the Lower End of the Humerus," by Dr. Oscar H. Allis, of Philadelphia; "Treatment of Fractures of the Lower End of the Radius," by Dr. P. T. Conner, of Cincinnati, and Dr. C. L. Bower, of Philadelphia; "Treatment of Fractures of the Neck of the Femur," by Dr. Bedford Brown, of Alexandria, Va.; "Treatment of Gunshot Fractures," by Dr. George A. Goodfellow, of Tucson, Arizona; "Treatment of Fractures of the Shaft of the Femur," by Dr. Llewellyn Eliot, of Washington, D. C.; "Treatment of Open or Compound Fractures," by Dr. H. H. Mudd, of St. Louis, and Dr. John B. Hamilton, of Chicago; "Effects of Obstruction in Urination upon the Bladder and Kidneys," by Dr. J. William White, of Philadelphia; "Diagnosis and Treatment of Enlargement of the Prostate Gland," by Dr. Hunter McGuire, of Richmond, and Dr. William T. Belfield, of Chicago; "Symptoms and Treatment of Stone in the Bladder," by Dr. William T. Briggs, of Nashville; "Symptoms and Treatment of Tumors of the Bladder," by Dr. John B. Deaver, of Philadelphia, and Dr. C. F. Buckley, of San Francisco; "Treatment of Stricture of the Urethra," by Dr. J. Rosenstirn, of San Francisco.

Longevity.—Dr. Archer Atkinson, of Baltimore, has succeeded in collecting from various reliable sources the names of some 250 persons who were known to have lived to the age of 100 years or more.

The American Surgical Association will hold its annual meeting in the lecture room of the Medical Department of the Columbia College, Washington, D. C., on May 29, 30, 31, and June 1, 1894.

Dr. John Ashhurst, Jr., will read a paper entitled "The Surgical Treatment of Empyema," the discussion of which will be participated in by Drs. N. P. Dandridge, C. B. Nancrede, T. F. Prewitt, and De F. Willard.

Dr. J. S. Billings will present a communication upon "Methods of Teaching Surgery," which will be discussed by Drs. J. C. Warren, N. Senn, W. W. Keen, E. M. Moore, W. T. Briggs, and Hunter McGuire.

Dr. L. M. Tiffany will read a paper upon "The Surgery of the Kidney," in the discussion of which Drs. M. H. Richardson, H. H. Mudd, C. H. Mastin, and Ford Thompson will take part. Summary: 1. Influence of disease of kidney on general surgery. 2. Nephritis. 3. Pyelonephritis. 4. Nephrolithiasis. 5. Nephrectomy, partial and complete.

Dr. W. W. Keen will read a paper entitled "Methods of Controlling Hemorrhage in Amputation at the Shoulder," as illustrated by three cases of amputation at the shoulder-joint and of the entire upper extremity, which will be discussed by Drs. Roswell Park, C. B. Porter, and J. William White.

Papers will also be read by Dr. Hunter McGuire and Dr. Joseph Ransohoff.

The Association of Military Surgeons of the United States will hold its fourth annual meeting in Washington, D. C., May 1, 2, and 3, 1894.

This national organization is composed of medical officers of the U. S. Army, U. S. Navy, National Guard of the United States, and the Marine Hospital-Service, and includes in its membership many distinguished surgeons. A brilliant and able literary program is promised. The afternoon of one day will be set apart for an object lesson from the *Manual of Drill*, by the Hospital Corps. The evenings will be given up to social entertainments. About five hundred delegates are expected to be in attendance.

Dr. Nicholas Senn, of Chicago, is President of the Association, and Dr. George Henderson, of Washington, Chairman of the Committee of Arrangements.

The Colorado State Medical Society will hold its annual meeting at Denver, June 19, 20, and 21, 1894. A cordial invitation is extended to members of the American Medical Association to attend the meeting, and those who expect to return East *via* Denver are invited to correspond with the Secretary, Dr. A. Stewart Lobingier, in order that an invitation to participate in the program may be extended and proper entertainment may be arranged.

Mikulicz, of Breslau, is under consideration as the successor of Billroth at Vienna.

Books and Pamphlets Received.

Seventh Annual Report of the Ophthalmological Department of the State Hospital for the Insane at Norristown, Pa. Ophthalmologist, Charles A. Oliver, M.D. Reprinted from the Thirteenth Annual Report, 1892.

Syllabus of Lectures on the Practice of Surgery. Arranged in Conformity with the American Text-book of Surgery. By N. Senn, M.D., Ph.D., LL.D. Philadelphia: W. B. Saunders, 1894.

PERIPHERAL FACIAL PARALYSIS.[1]

BY MARIA M. VINTON, A.M., M.D.,
OF NEW YORK.

PERIPHERAL facial paralysis, of Bell's type, so-called, is one of the most frequently met of nervous lesions, aside from those that are called functional. It results from a neuritis of the facial nerve, either external to the stylo-mastoid foramen or within the aquæductus Fallopii. During ten years of clinical work in the Nervous Department of the Manhattan Eye and Ear Hospital fifty-two cases of this affection have been treated. These cases have all received electric treatment only, aside from the regulation of the general health, and they show conclusively the value of such treatment, if persistently carried out, in securing the cure of the affection or a marked degree of improvement.

The facial nerve, from its anatomic relations in its course from the brain to the face, is peculiarly exposed to influences producing neuritis. Arising from a nucleus in the floor of the fourth ventricle, it makes its exit from the medulla in the groove between the olivary and restiform bodies, just behind the pons. It passes forward and outward upon the crus cerebelli and enters the internal auditory canal lying upon the auditory nerve. This close relation with the nerve of hearing often determines a common lesion of both nerves in the canal. At the bottom of the meatus it enters the aquæductus Fallopii, and follows its course as it curves downward behind the tympanic cavity, in the substance of the temporal bone. It is there exposed to the influences of pressure and inflammation extending from a diseased middle ear; and it is peculiarly liable to pressure from its course, as it lies in a small bony canal which gives no room for the swelling accompanying inflammation of its sheath, so that a very moderate degree of inflammatory action may determine sufficient pressure to destroy the function of the nerve partly or entirely.

In the upper part of the canal, through the Vidian nerve and Meckel's ganglion, the facial nerve supplies the levator palati and uvula, and taste-fibers to the tongue. A lesion here, according to some authors, causes paralysis of the palate; a lesion beyond this point leaves the palate normal. Just beyond this point the nerve enlarges to form the geniculate ganglion, from which rises a tympanic branch, supplying the stapedius and laxator tympani muscles. A lesion here is accompanied by paralysis of these muscles, and an abnormally tense tympanic membrane, causing the rare symptom of hyperacusis or exaggerated hearing.

As the nerve passes vertically downward behind the tympanic cavity it gives off the chorda tympani nerve one-quarter of an inch before its exit from the stylo-mastoid foramen. This nerve supplies filaments to the submaxillary gland and carries taste-fibers to the gustatory nerve. A lesion between here and the geniculate ganglion gives absence or alteration of taste on the corresponding half of the tongue anteriorly, and dryness of the mouth. Just within the foramen the nerve sends branches to two muscles of the external ear. It supplies motion to the entire side of the face, the stylo-mastoid muscle, and the posterior belly of the digastric. A lesion at any point in its course gives rise to paralysis of the entire corresponding half of the face.

A lesion in the brain itself, internal to the nucleus in the fourth ventricle, affects only the muscles about the lower half of the face, leaving the eye normal; while an extra-nuclear or peripheral lesion involves the eye also. In intra-nuclear lesions voluntary power is more affected than emotional movements, and there is no degenerative reaction or atrophy of muscles, thus following the rule for cerebral paralysis. In peripheral lesions we have a more or less marked reaction of degeneration in nerve and muscle and muscular atrophy. I propose to speak only of extra-nuclear or peripheral lesions.

According to the examination of my cases, the commonest cause of facial paralysis is cold, there being eighteen cases in which some form of exposure, followed by pain and soreness in the side of the face, had preceded paralysis. Common examples of this cause are the following: sleeping under an open window; sitting, in winter, at work by a loose sash, through which the wind blows; riding in cars in a draught after exertion; sleeping out after a debauch. Here a neuritis or a perineuritis exists within the Fallopian canal, or near the exit of the nerve from the canal. Paralysis generally occurs within twenty-four hours from the time of exposure, the patient often going to bed well and waking in the morning with a "crooked face."

[1] Read at the December meeting of the Alumnæ Association of the Women's Medical College of the New York Infirmary.

The second cause, in point of frequency, is disease of the middle ear, with or without abscess. I find records of twelve cases in which for weeks or months there had been inflammatory action going on in the middle ear or mastoid cells, and pressure from swelling or extension of inflammation had finally reached the facial nerve and caused paralysis. In three of these cases the paralysis followed operations. In Case XI there had been an operation for mastoid disease. Case II followed removal of carious bits of bone from the external auditory meatus. Case LII had been entirely deaf for some years. She was advised to have the ossicles removed, in the hope of giving her slight hearing, and was told that the operation could not do her any harm, and benefit might be gained. Great was the disgust of the young lady to find her beauty spoiled by a complete paralysis of the side of her face corresponding to the operation. This shows how careful operators should be in their operations in so small and delicate a cavity as the tympanum.

Two patients had fracture of the skull. Case XXV fell from a height of three stories and sustained a fracture of the skull, which resulted, among other things, in facial paralysis. Case VI was a marble-worker. While standing near the wall of the yard several slabs of marble which leaned against the wall fell over, knocking him down and fracturing the skull and left arm. He was unconscious in the hospital for some days, and on regaining consciousness was told that his face was crooked. This case was a very marked one at first, and has improved very much after six months of careful electric treatment. He can now close the eye and make nearly all the lip-movements normally.

Case IX followed the formation of an abscess on the side of the head resulting from a blow above the ear. The abscess was not opened until some time after suppuration occurred. The pus probably burrowed downward. Neuralgia came on, followed by trismus and facial paralysis from involvement of the facial nerve in front of the ear. There was at no time any trouble with the internal or middle ear, and the suppuration was entirely external to the skull.

Case V gave a clear history of syphilis of some months' duration. He had severe head-pain for several weeks, then suddenly-occurring deafness in the left ear and left facial paralysis. The auditory and facial nerves were probably implicated together in the interval auditory meatus by a specific inflammation.

Case XIX had double facial erysipelas, affecting both auricles and extending up into the meati auditorii. At the end of three weeks deafness and facial paralysis appeared on the right side, and after three days the same occurred on the left. The reaction of complete degeneration was present on the left side, and no improvement resulted from treatment, while on the right the reaction showed less marked degeneration, and partial recovery occurred. Here, as in the last case, the nerves of hearing and of motion to the face must have been implicated in their course together. The deafness was complete and permanent on both sides.

In twelve cases no cause could be found for the occurrence of the paralysis; there were no prodromal symptoms, and the paralysis appeared suddenly, the patient going to bed well and waking in the morning with the typical symptoms.

There seems to be no preference for either side of the face, cases being nearly equally divided between the right and left sides. Two cases were bilateral—one from facial erysipelas, and one from double-ear disease. The cases occurred about equally among males and females, and occasionally among children. Five of my cases were in children: one in a girl of nine years, following middle-ear disease; three in infants, with unknown cause; one in a case of anterior poliomyelitis, the nucleus of the seventh nerve being affected as part of the prolongation of the anterior columns of the cord upward.

Symptoms. The affected side of the face is immovable and expressionless, the eye widely open without power to raise the lower lid; the upper lip and cheek cannot be drawn up or the forehead wrinkled; all the lines of expression are smoothed out of the face, and the angle of the mouth droops. The opposite side overacts, drawing the mouth away from the paralyzed side. This condition is very marked during speech and attempts to smile or weep, the flat and expressionless side contrasting forcibly with the contorted healthy side. The unclosed eye becomes red and irritated from the effects of wind and foreign particles, and from the dryness produced by inability to close it, and I have seen one case of ulcer of the cornea result. The labials cannot be pronounced correctly, from paralysis of the lip-muscles, and the patient cannot whistle or blow out a candle, from implication of the orbicularis oris. Food lodges in the cheek from paralysis of the buccinator, and the naris does not dilate in forced inspiration. Patients often complain that the face was swollen when the trouble began, but this swelling is only apparent, owing to the drooping and flattening of the cheek. Prodromal symptoms, such as pain, neuralgia, soreness of the side of the face, tinnitus and deafness often occur, especially when the cause is exposure or ear-disease. Deafness occurred in nineteen cases, twelve of which resulted from middle-ear disease.

Gowers throws considerable doubt on the occurrence of paralysis of the palate from disease of the facial nerve. He examined over one hundred

cases without finding one undoubted case of paralysis of the palate. I find in my fifty-two cases no record of paralysis of the palate. One case only is reported as having difficulty in swallowing, but with the arches of the palate even. Cases V and XIV must both have had lesions of the nerve above the point of emergence of the fibers for the palate, yet neither complained of any symptoms referable to the palate.

I find two cases in which there was alteration of taste due to a lesion of the chorda tympani nerve. Case XXIII had a metallic taste in the half of the tongue on the paralyzed side. Case LII had absence of taste on the anterior part of the tongue on the paralyzed side. Thus we see that of these fifty-two cases, all but three were probably produced by inflammations in the lower part of the Fallopian canal or on the side of the face just external to the canal.

Before passing on to the treatment and its results, let me notice a few of the more interesting cases:

Case XLVIII.—C. H., a gravel-roofer, thirty-nine years old, has always been a perfectly healthy man; he remembers no sickness, and denies venereal diseases, but was a user of alcohol and tobacco to excess up to nine years ago. He is at present the picture of health. Eight years previous to his coming under observation he began to have facial convulsive tic; the spasm involved the whole left side of the face. At first it was only occasional, and involved only part of the face; later it became very annoying, being constant even during sleep. He came first to the Eye Department, and had a small amount of hypermetropia corrected by glasses, with benefit to the tic for a few days. The spasm returned as annoying as before, and he was brought to the nervous department. After observation for one week his nose was examined, and a spur found on the left side of the septum. This was removed, with the same temporary benefit as before. However, he soon returned unimproved. He was now told that the operation of nerve-stretching of the seventh nerve would probably give him at least temporary relief, causing however facial paralysis. He gladly agreed to the operation, and on January 5, 1893, Dr. Terriberry made an incision below the ear, and with a strabismus-hook stretched the nerve, using about five pounds of force, and exerting it until the faradic current applied to the nerve gave no contraction in the facial muscles. There resulted complete peripheral facial paralysis and complete relief from the tic, with which the patient expressed himself very much pleased. His facial paralysis ran the usual course of a mild type; the reaction of degeneration was never marked, the faradic current giving slight contraction in the muscles through the nerves, and galvanism giving contraction with normal formula. In four months voluntary control was normal in the face. At present, more than a year from the operation, the tic is still absent. During the past month he has had spasm for a few seconds several times. Up to last month no tic occurred at all.

Case XV.—Margaret W., sixty-six years old, a German widow, had had four children, all of whom were living and well. She had never had any miscarriages, had always been well, and remembered no illness other than normal childbirth. She gave no history of syphilis, and the family history is of no importance. She was first seen in October, 1891. In the previous January she noticed a "pimple" on the left cheek, near the angle of the jaw, which soon became a patch of vesicles filled with clear fluid. They remained thus for two months, then broke, discharged a watery fluid, and dried, forming superficial cheesy flat masses covered by thin crusts. She then began to have pain, starting at the seat of the eruption and extending over the side of the face and upon the scalp, but not involving the infra-orbital region. The pain was not darting in character, but steady, and more of the character of neuritic pain. It became so severe that she was obliged to take large doses of laudanum to obtain any relief or sleep. Pressure over the exit of the branches of the fifth nerve showed no tender spot, and manipulation of the face gave no increased pain. Six months after the appearance of the vesicles, and four from the commencement of the pain, a complete left-sided facial paralysis occurred of Bell's type. This was later followed by trismus, and the patient was unable to separate her teeth more than half an inch, or to chew solid food. There was no anesthesia or analgesia of any part of the face or head. When I first saw her the face was much drawn to the right, showing the completeness of the paralysis, there being absolutely no resistance by the muscles of the left half of the face. The skin of the affected side was shiny, and none of the lines of expression remained. There was no paralysis of the palate or alteration of taste. Sight and hearing were normal, as well as the sense of smell. The eye-muscles were normal. At this time the eruption formed a patch the size of a half-dollar over the cheek just above the angle of the jaw. It was dry, flat, whitish, with pigmented spots; showed no ulceration and no discharge; was slightly raised above the surface of the skin, and had a slight, red areola; it was not painful or tender. There were no enlarged glands in the neck. Aside from the pain and facial paralysis the patient was well, though worn by pain and fasting.

Dr. G. T. Jackson presented the case to the New York Dermatological Society. No member ventured a diagnosis of the skin-lesion.

Dr. A. R. Robinson said he had seen a similar eruption in a case of cerebral hemorrhage.

Dr. Piffard suggested that it might be tuberculous, and Dr. Bulkley thought it well to try anti-syphilitic treatment. Accordingly the cheesy superficial mass was examined for tubercle-bacilli, with negative results.

The patient would not permit the removal of a portion of the skin for examination. She was then put on mixed treatment, the solutions increasing in strength, as recommended by Dr. Bulkley. At the same time aconite was used for the pain, with slight relief.

Dr. William R. Birdsall examined the case with reference to the nervous lesion, and expressed the

opinion that we could locate no lesion other than that of peripheral facial paralysis, the seventh nerve being affected within the aquæductus Fallopii. The fifth nerve was not implicated in all of its branches, and there were no symptoms of a lesion of other cranial nerves. He thought that the pain and trismus were reflex symptoms.

The members of the Dermatological Society had concurred in calling the skin-lesion a "neurosis." The reactions of complete degeneration in the nerve and muscles of the face were found on testing with electricity.

Galvanism was applied to the facial muscles. At the end of six weeks of anti-syphilitic treatment Dr. Bulkley considered the skin-lesion to be improved. It had dried some, and in parts seemed to have been absorbed. This seemed to me to be no greater change than had occurred in the time before this treatment was instituted. There was now a chain of enlarged lymphatic glands extending from the angle of the jaw to the clavicle. In other respects the patient remained unimproved, the facial paralysis remaining the same, and the pain constant and intense.

I now lost sight of the woman, and learned later from her daughter that she had gone to an institution in New Jersey, where she remained until her death, in August, 1892. At the time of her death all the conditions present when I last saw her had remained the same, and when her daughter last saw her "there were sores all over her face." The death-certificate stated that she died of "paralysis of the face and throat," but the daughter was given to understand that she had "cancer." I could not learn whether an autopsy was held—in all probability there was none. Thus the later history did not clear up the diagnosis of the cause of her various symptoms.

The prognosis and treatment of cases of facial paralysis depend much on the amount of damage to the nerve that has occurred. A clue to the results to be obtained is given by the electric reactions found in the nerve and muscles affected. These cases may be divided into three classes:

1. Mild cases, which recover in a few weeks. Here, at the end of ten days both muscle and nerve contract to faradism and galvanism, the latter giving normal formula, *i. e.*, C C C > A C C.

2. More severe cases, which recover for the most part completely after from four to eight weeks' treatment. Here there is diminished reaction to faradism and galvanism in the nerve; in the muscles increased excitability to galvanism and A C C = or > C C C.

3. Severe cases, which recover only partially after months of careful treatment. Here there is no contraction to galvanism or faradism in the nerve, while there is loss of faradic excitability in the muscles with reversed formula, and increased excitability to galvanism—in other words, complete degeneration-reaction.

These cases are followed by contracture of the facial muscles and fibrillary twitchings. I am now treating a case in which after five months' treatment the connective-tissue bands in the cheek feel like a band of iron when the finger draws upon them within the mouth. Another case complained of facial tic following paralysis.

Voluntary power begins to return before the electric reactions become normal, and the eye recovers more completely than the mouth. This is explained by Gowers as due to the intimate connection between the innervation of the orbicularis palpebrarum on the two sides, the nerve-power regenerating from the sound side.

In my fifty-two cases electric treatment alone was used, with the following results:

Complete recovery is recorded in eleven cases. Of these degeneration-reaction was slight in five cases, moderate in four, and marked in one. Treatment was begun early in all of these cases and continued for from two to five months. We use faradism in all cases in which it gives any reaction in muscle or nerve, applying a flat sponge on the back of the neck or palm of either hand, and an interruptor over the facial muscles. In many cases a reaction will be found by using a laryngeal electrode inside the cheek when none is produced with the sponge on the skin. We also use galvanism in these cases, and in all those that do not respond to faradism. For the galvanic current the electrodes are used in the same positions, the pole which gives strongest contraction being rubbed over the muscles in electric massage, or an interruptor is used. A sufficient current is used to produce moderate muscular contraction, and which at the same time is easily tolerated by the patient. The application is made from five to ten minutes three times a week. In private practice electricity may be used with advantage every day. Gowers states that electricity produces no effect on the regeneration of the nerve, but keeps up the tone of the muscles and prevents atrophy, so that as soon as any nerve-power is regained the muscles are ready to act. It is very noticeable how electricity wakes up contraction and voluntary power in neglected cases after its use for a week or more.

In twenty-seven cases improvement more or less marked is recorded. In ten cases the improvement was marked, amounting almost to cure. Of these, three showing marked degeneration-reaction received treatment from three to eight months and were nearly cured; while four others with moderate degeneration, who should have recovered under treatment, but neglected it, had only slight improvement. Two with slight degeneration, but neglecting treatment, only partially recovered.

Of the sixteen cases that were only slightly improved, most went entirely without treatment or

neglected it until so late that marked benefit could not be secured.

To sum up, our work indicates that electric treatment should be begun early and carried out regularly and persistently for from two to eight months, or until a cure is secured. As soon as marked contracture has occurred, the use of electricity should cease, as it then only intensifies the drawing of the face to the paralyzed side. The results of such early and persistent treatment will give a greater number of cures, and a greater degree of improvement in other cases, than will result without the use of electricity. In such a lesion the cosmetic effect is highly important to the patient, as well as the rapid return of power to cover the conjunctiva, to properly control the food, and to pronounce the labials.

160 East 36th St.

SHALL THE TERM AUTO-INFECTION BE RETAINED?

By J. T. DUNCAN, M.D.,
professor of anatomy, women's medical college, toronto.

The subject of auto-infection (the endogenetic origin of puerperal fever, as Barnes now prefers to speak of it) is prominently before the profession again, both in America and in Europe. In the New World it has been brought forward by Williams in an admirable paper,[1] and in the Old World by the address of Robert Barnes before the British Medical Association. Williams holds that auto-infection is possible in a large proportion of cases, but admits that its actual occurrence is very rare. Barnes, on the other hand, while appearing to doubt its very existence, yet proceeds to describe it, and is of the opinion that it occurs frequently. These authorities, however, differ essentially in their conception of what endogenetic puerperal fever is. Barnes holds that it may be caused by a chill or other abnormal condition of the system, while Williams strictly maintains its bacteriologic origin. A vast amount of the doubt and difficulty that now surround this subject will be cleared away if we can accept the latter theory. And it appears to me, after careful consideration of the subject, that not only is it permissible to hold this theory, but that the evidence produced compels the most unequivocal acceptance.

This being the case, the definition of puerperal disease is easily given. Puerperal infection (following Williams) is simply the infection that leads to surgical fever. It is produced by the same micro-organisms and manifests itself in similar ways. "In other words, puerperal infection is wound-infection." As a corollary to this it may be stated that there can be neither wound-infection nor puerperal infection without the presence of pus-producing organisms. It follows from this again that no matter what the condition of the patient may be, no matter how much fever, for instance, may be found in a patient after confinement—if that fever be not caused by absorption of pus-producing organisms—then that fever is not true puerperal fever.

For the purposes of this article it will be unnecessary to go over the bacteriology of the subject further than to say that the principal microörganism causing puerperal fever is the streptococcus pyogenes, while in rare instances the staphylococcus, the gonococcus, and even the colon-bacillus may produce it.

The exclusively bacterial origin of puerperal disease being admitted, the question of auto-infection will depend entirely upon the presence of the organisms named in the genital canal before confinement. For if there be no pus-producing organisms in that canal, there can be no endogenetic puerperal fever.

Those who have not followed this subject of recent years will not be inclined to assent to this proposition. For many causes have been given for auto-infection, and the older physicians will not feel disposed to cast them all aside at once. The logic of events, however, will necessitate the theory of all of these causes to be abandoned. The following is a condensed list taken from a recent standard work on obstetrics:[1]

1. Absorption of effete matters (not pus-producing).
2. Excessive muscular action.
3. Deficiency of the excretory organs.
4. The effects of difficult labor.
5. Decomposition of retained placenta, clots, or lochia.
6. Cold, or exposure.
7. Shock, or emotion.

To state these causes is to show their inapplicability. Not one of them takes into account true infection. Even the portion of retained placenta is not a cause, for any fever caused by its decomposition would be exogenetic in character, not endogenetic. As a matter of fact, these causes are now largely abandoned, even by those who so recently advocated them. Barnes himself seems to have relegated them to obscurity—with one exception. That exception (as we shall see further on) has to do with deficiency of excretory power.

If, therefore, these authorities no longer insist on the foregoing as causes, everyone will soon cease to think of them as being, in any case, sources of origin of endogenetic puerperal fever. These causes

[1] "Puerperal Infection considered from a Bacteriological Point of View, with special reference to the Question of Auto-infection." by J. Whitridge Williams, M.D. American Journal of the Medical Sciences, July, 1893.

[1] Galabin's Midwifery, 1886.

being eliminated, only one possible source of auto-infection remains, and that is, as stated, the presence of pathogenic organisms in the canal before confinement.

That streptococci (and other pus-producing organisms) do exist in the canal before confinement is fully admitted. They are present in many pregnant, and apparently healthy, women. Williams remarks in regard to this subject: "Pathogenic organisms may exist in the genital tract during pregnancy without giving rise to any symptoms whatever, and only exert their influence during labor or the puerperium, when the wounds which follow labor will afford abundant opportunity for their absorption."

Nothing can be more plain than this. Bacteriologists believe that the pathogenic microörganisms in the canal produce no harm till the surface is lacerated during labor. Then they are absorbed, the result being puerperal fever; and this, because the streptococcus dwelt in the body of the patient before confinement, they consider to be auto-infection. But is such a deduction justifiable? That streptococci are present in the canal all will admit. But they are foreigners—coming from some external source—never originating in the canal, and never becoming part of the body of the bearer. We must deny, then, that these foreigners can ever produce endogenetic puerperal fever. On the other hand, any fever caused by them would be strictly exogenetic—as truly so as though these same microorganisms infected a wound on the external surface of the body. So plain does this appear to be, that it is misleading to use the term auto-infection in such a case.

But, leaving aside this objection to the term, a more important inquiry is: Are those streptococci in the canal ever a cause of puerperal fever—in other words, are they ever infective? This question has not yet been answered in the affirmative. But can it be answered in the negative? We believe it can. We believe that the streptococci in the canal are not infective unless made so by external assistance. If this position can be maintained, it will be seen that a case of endogenetic puerperal fever is an impossibility. As tending to support the position taken I submit the following records from my own practice.[1]

Case I.—Mrs. M., multipara, was a healthy and vigorous subject. Her surroundings were excellent and the nursing unexceptionable. To accomplish delivery it was found necessary to pass the hand into the vagina, the fingers into the uterus, and to use the forceps through the os. Convalescence was uninterrupted. The pulse and temperature were normal throughout, the temperature never rising above 99°. The record was kept until the ninth day.

Case II.—Mrs. G., primipara, was a healthy, strong young lady. Her surroundings were good. The hand had to be introduced as in the first case, and the forceps used high up, passing into the uterus. Recovery was excellent. The pulse and temperature were normal throughout. In this case the perineum was considerably lacerated, but was drawn together immediately by carbolized silk sutures.

Case III.—Mrs. M., a multipara, with good surroundings, had fairly good health at confinement. The head was well down before the forceps was used, but it was passed into the uterus. The temperature never went above 99°, and an excellent recovery followed.

Case IV.—Mrs. A., a multipara, had poor, uncleanly surroundings. The hand was passed into the vagina. There was a breech-delivery. The woman made a good recovery, the temperature never rising above 100°.

Case V.—Mrs. O'N. was a multipara. The hand was passed into the vagina and the fingers into the uterus. The forceps was used through the os at the superior strait. Recovery was a little slow, but good. The temperature never rose above 100°.

Case VI.—Mrs. S., a primipara, was a healthy young lady, whose surroundings were excellent and she was well nursed. The hand was introduced into the vagina, the fingers through the os, and a breech-presentation diagnosticated. After a considerable time delivery was assisted by a soft fillet. All efforts to deliver the head were futile at first; asphyxia threatened, and to save life the forceps was rapidly applied and the head extracted. A considerable laceration was the result, which was stitched. The temperature and pulse remained normal throughout.

Case VII.—Mrs. H., a multipara, was far from strong. The building in which she lived was a portion of a stable. It was cleanly kept, but the odor of manure was manifest through every room of the house. The hand had to be introduced into the vagina as in the other cases, the forceps being passed into the uterus. Recovery was good, the pulse and temperature remaining normal.

Case VIII.—Mrs. H., a multipara, was a woman of nervous temperament, stout, with flabby and soft flesh. The anus opened into the vagina, all stools being extruded through the vulva. At confinement the whole hand was introduced into the vagina, and the fingers and instruments into the uterus. In this case, interesting by reason of the anatomic peculiarity, the variations of pulse and temperature were noted with the greatest care. The pulse and temperature, however, were perfectly normal throughout. The temperature never rose above 99°. The patient got up without permission on the eighth day because she "felt so well."

Case IX.—Mrs. F., a multipara, was a strong, large woman, the surroundings not being of the best. She

[1] These records cover a period of four and a half months, and include only those in which the labor was severe, those in which, for one reason or another, it was necessary to pass the hand into the vagina.

had miscarriage at three months. Chloroform was given and the hand passed into the vagina, and the uterine contents scooped out by the finger. They were very offensive. The uterus was irrigated with carbolized water. This was a case of pre-partum infection, the pulse being 100 and the temperature 99° on the day of first attendance. The temperature went up to 99⅘° on the third day, afterward remaining at 99° until attendance ceased.

Case X.—Mrs. M., a primipara, was a healthy young lady. The surroundings and attendance were excellent. At confinement the hand was introduced, the fingers entering the uterus. The forceps was applied at the superior strait. There was a small laceration, united by suture. I may note that the child was stillborn, and the breasts, as a consequence, were rather troublesome. In this case I give the daily record: September 8th, pulse 70, temperature 98⅖°; 9th, pulse 88, temperature 98⅘°; 10th, pulse 88, temperature 98⅕°; 11th, pulse 88, temperature 98⅕°; 12th, pulse 96, temperature 99°; 13th, pulse 84, temperature 98⅖°; 14th, pulse 72, temperature 98⅕°; 16th, pulse 72, temperature 98⅕°; 18th, pulse 64, temperature 98⅕°.

Case XI.—Mrs. I., a multipara, was not strong; her surroundings were clean. The hand was passed into the vagina, the fingers into the uterus, the forceps also into the uterus. In this case the temperature did not vary on any day more than one-fifth of a degree above or below the normal line. The pulse also was normal throughout.

In all of these cases daily records were kept of the pulse and temperature.

Evidence such as the foregoing, though negative, is strong. Presumably in many of these cases the streptococci were present in the canal. And yet, although the labors were, as a rule, severe, although examinations were frequently made, although the instruments were passed into the uterus itself, and air necessarily freely admitted, in none of them were the streptococci virulent. Does not this point to the conclusion that they will not become infective without extraneous assistance?

But in addition to many such records which could be produced by the obstetricians of this continent, let us look at some investigations by European experts. Merman (quoted by Williams) in 900 cases did not douche the vagina, yet had so little fever that he thinks there is no room for the idea of auto-infection. Leopold, of Dresden, in a series of cases had only one-fifth of 1 per cent. (1 in 500) in which the fever could have been due to auto-infection. Surely such records go far to prove that the streptococci of the canal will not of themselves become infective.

Again, the remark by Smyly, of Dublin, at the late meeting of the British Medical Association, confirms what has already been said. This was to the effect that women do best who are delivered on the street. In other words, women are not possessed of infective streptococci. The fact is, that Nature has wonderfully provided against danger of infection through the birth-canal. In the first place, streptococci are not found in the majority of women, owing, no doubt, to the fact that the fluids of the canal destroy these organisms. In a considerable number of women, however, streptococci are found, but appear to have lost their infective power. Then at confinement, even those in the canal are swept away by the fluids, or forced out by the head or the placenta. After confinement, the canal is kept freed by the abundant outflowing lochia—the lochia being usually free from all pus-producing organisms.

It would appear, then, that Nature has done her part well. She has made every provision against auto-infection, and it would be a libel upon her to say that she had provided for the possibility of it.

But here we see an illustration of man's power for either good or evil. If his assistance be needed, and he refrains from introducing deleterious matter into the vagina, he does good, and no fever results. If, on the other hand, the woman receives noxious matter from his finger or instrument, then what evil may ensue! As to what the deleterious matter may be which is introduced, while occasionally we know what it is, in the great majority of cases we do not know. Williams says in regard to this: "It appears then that beside the presence of micro-organisms, certain conditions, of which we are yet ignorant, are necessary for the production of infection. . . . It is possible that the organisms which grow in the vagina lack (certain) materials, while those which are introduced directly from without possess them."

Whether these materials are products of bacterial life (as Williams seems to think) or other pabulum necessary to produce infection, we know not. Certain it is, however, that man frequently introduces what is necessary to make the bacteria already there infective, or actually introduces infective organisms. The result is true puerperal disease. And how often, after having himself done an evil, does the author of the mischief shelter himself with the statement: "It is a case of auto-infection?"

One word in regard to that form of fever of which Barnes speaks as endogenetic puerperal fever. The first step in this process he holds to be absorption of the materials that normally have to be taken up by the system after confinement. After describing this he says: "So far there is no poison, no sepsis, but the absorbed matter has to be disposed of in one of two ways: 1. Undergoing normal metabolism, it is used up in the formation of new tissue and in the secretion of milk. 2. The residual portion, not so converted, has to be eliminated by the excreting organs. Now suppose that this healthy process is checked, the retained matter, missing its

proper metabolic changes and destination, undergoes other changes of a noxious character, engendering fever. Here we have the simplest types of endogenetic septicemia."

From this description it is evident that no pus-producing organisms have produced this form of fever. It is produced only by deficiency of excretory power. This condition may be caused by a chill, or other means. Now, whether or not there be room for dispute as to what form of fever this is, it can at least be positively stated that it is not true puerperal fever, which can only be originated by the absorption of streptococci or other pus-producing germs. We believe, then, that auto-infection in any form does not exist, and that, therefore, the term should not be retained.

It may be asked whether any practical benefit will result from the elimination of the word from the obstetric vocabulary. Among other benefits, its elimination will entirely prevent all pre-partum douching of the vagina. For if there be no auto-infection, this measure of "meddlesome midwifery" would no longer be used. It is useless to remove non-pathogenic organisms.

In the second place, the absence of this term should lessen the amount of careless midwifery. So long as it is retained, so long will careless obstetricians have a way of escape from the consequences of their own want of care. That it is sometimes impossible for the attendant to prevent puerperal fever all will admit. He can, however, avoid conveying streptococci or the pabulum necessary for their support into the canal on his hands or instruments. And if the patient is not thus infected, it is seldom indeed that she will be infected, either from the atmosphere, erysipelas, or other cause. Auto-infection being non-existent, the obstetrician should not have the term behind which to shelter, and once let it be fully understood that auto-infection does not exist, the stress of circumstances will certainly tend either to improve the methods or else lessen the practice of all obstetricians who have not fully equipped themselves for the responsibility of their important duties.

A PROPOSAL IN THE INTERESTS OF HIGHER MEDICAL EDUCATION.

By BAYARD HOLMES, M.D.,
of Chicago.

The annual session of our medical schools for 1894 is drawing to an end. A few educators are planning for the new year. Many are dissatisfied with the results of the past, with the methods now in vogue, with the traditions and the present practices of medical teaching. These are the ideas of one of the dissatisfied, of one who believes medicine deserves better things from education, of one who believes in the possibility of improvement. Cannot one or several of our best medical schools adopt such a program as the following:

1. Admit only such students as are already admitted to their respective junior classes in the regular college course; and have in addition credits for (1) chemistry, theoretic and analytic; (2) for biology, one year of laboratory work; and (3) a reading knowledge of French and German.

2. Give to each student, when he completes *two years' work* in the medical course, the A.B. degree.

These requirements for admission and the privilege of the A.B. degree on the completion of two years' work are rational concessions. Any one of the universities for which this is written would have students enough, and, with a proper *quality* of medical teaching, the A.B. degree would not be cheapened thereby. It must not for a moment be supposed that the quality of the first two years of the medical course as now conducted is worthy of such recognition, but the material of that course is not wanting in educational powers. It needs simply better teachers and better methods.

The reason the medical man should begin his professional study so soon depends upon the fact that so much time is required for hospital practice, for travel abroad, and for apprenticeship practice before the real work of the physician's life begins. It is for these reasons that the university is asked for this just concession.

The university body should have no less direction and control of the medical school than it has of the school of history.

Should anyone urge that the poorer communities and the sparsely settled districts need doctors, but cannot command men of such culture and education as are here proposed, he must be reminded that the supply of men fitted for these communities now greatly exceeds the demand, and that there will still be left one hundred and fourteen medical schools supplying this field.

The reading of French and German is necessary to an improvement in the method of teaching as proposed in the next paragraph.

3. Abandon the traditional lectures, which now, by monopolizing, disgrace our medical teaching, and introduce the seminar and the individual laboratory method into every department.

This may need a word of explanation. Lectures are proper for such instruction as is otherwise unattainable, for general instruction on topics of the moment, and for laying out work. Students should have, for example, laboratory and recitation work on the bones. This should be accompanied by a very few lectures and by seminars as often as once a week for each student. For such work *material,*

a library, and *a teacher* (not a lecturer) are necessary. An amphitheater is not necessary, but a laboratory, roomy, well equipped with desks, lockers, and instruments, is necessary. The students should follow a syllabus and use pencil, paper, measures, saw, scales, and many other simple instruments.

Anthropometry should be begun on the students themselves. It is not necessary or desirable that all students should do the same work at the same time. Each student should advance through the work required in his outline as slowly or as rapidly as his abilities and industry permit. The teacher should satisfy himself that each unit of the work is done by any student and the educational object attained before credit is given him. This is contrary to the traditions of our medical schools and to the practice of English and Scotch colleges, but it is the only way in which any of our students learn anatomy now. I have seen a hundred students working quietly and industriously in a microscopic laboratory on this very plan—no bustle, no confusion, nothing but the orderly noise of earnest work. This method is equally adapted to physiology, to materia medica, to surgical pathology, to clinical surgery, to medicine, to clinical medicine, and to operative surgery. All small clinics, and hospital clinics even, should be conducted on the seminar method, *i. e.*, individual research and criticism in small classes.

It would be desirable to tear out the amphitheaters (all but one in each college), upon which we now pride ourselves, discharge the medical orators and rhetoricians, and secure in their places class-rooms, libraries, and teachers of medicine.

It may be objected that this method is not adapted to large classes. It is not adapted to classes at all. It is adapted to students and to almost any number. It is true that by this method a teacher could do his subject and his pupils justice, only by limiting the number of students, but the same limitations apply to the rhetoric method, if good work is insisted upon. Many of these objections are removed by the next suggestion.

4. Divide the school year into short terms of three months each, at the beginning of any one of which the student may begin his work, and at the end of any one of which let him receive his credits or his degree.

The advantages of such a division of the year are already recognized in the under-graduate departments. To an executive educator, the advantages are evident. The medical students are as much entitled to these advantages as the students of Hebrew or political economy. Smaller laboratories will accommodate a class, if one section does the work one term, and another section the next term. A student who fails to graduate now at the appointed spring commencement is disgraced. With the short-term plan, he would not be tempted to hurry on and slight his work, for he could graduate three months later. One teacher can carry through three times as many students equally well on the short-term plan as he can if his work is extended over the whole year.

5. Make the course of study conform to such educational requirements as prevail in other departments of the university, *i. e.*, abandon the iron-clad course of study and substitute a liberal margin of elective work under the supervision of a dean. By this means students would be able to pursue extensive studies in limited fields with a minimum of work in all other departments and thus add greatly to their efficiency as specialists, as scholars, as teachers, or as investigators.

It may be objected that, conducted under such plans, the medical school would not pay. In answer, it is suggested, that there is no more reason why a medical school should pay, than there is why a school of sociology should pay. It is not necessary and it is unjust to conduct a *quasi* medical school so as to earn a few thousand dollars for the university, to be expended in other departments or work.

It may be objected that the present faculties are not able, with their poor pay and their other arduous duties, to conduct such a course of instruction, but it must be remembered that the resources of the community are not yet entirely exhausted.

If medical schools are *educational* institutions and not *business* adjuncts, why should not such modest suggestions as these be even surpassed in forthcoming announcements? It is only by making the medical schools the peers of the best-conducted educational institutions that endowments for them can be expected. It is as absurd to have a medical college attached to a university, as many of them are attached to-day, as it would be to have a special business college in the same relation. In this matter the profession has a right to expect such institutions as, *e. g.*, Harvard, Columbia, and the University of Pennsylvania, to lead.

There are reasons, however, for believing that they will not lead unless they begin soon. The University of Minnesota has during the past year secured a support which makes its future development, under ordinary management, secure. Michigan has now taken advanced ground. But the most hopeful trend of medical education lies in the coöperation of the State Board of Health and the medical school. The University is made to feel the needs of the State Board of Health and it attempts a larger amount of laboratory teaching of State medicine and hygiene than is offered elsewhere. The State also possesses many other functions which will, no doubt, soon be utilized in the

instruction of medical men. The hospitals for the insane, the institutions for the blind, those for the deaf, those for the feeble-minded, the jails and prisons ought to be open to university students as laboratories for investigation and study. Such laboratories none but State universities can ever possess, and such student-supervision would be more powerful for good than a State charities aid society.

ORIGINAL ADDRESS.

THE ARMY SURGEON.[1]

By WILLIAM OSLER, M.D.,
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

General Schofield, Mr. Surgeon-General, President Alden, and Professors of the Faculty: At the outset I am sure you will permit me, on behalf of the profession, to offer to the Army Medical Department hearty congratulations on the completion of the arrangements which have made possible this gathering. With capacities strained to the utmost in furnishing to students an ordinary medical education, the schools at large cannot be expected to equip army surgeons with the full details of special training. A glance at the curriculum just completed brings into sharp relief the disabilities under which previous classes must have proceeded to their labors, the members of which have had to pick up at random—in many cases have probably never acquired—the valuable knowledge traversed in the lectures and laboratory exercises of the session. But greatest of all the advantages of an army medical school must be counted the contact of the young officers with their seniors, with the men under whose directions they subsequently have to work. In comparison with their predecessors, with what different feelings and ideas will the men before us enter upon their duties in the various posts to which they have been assigned. Instead of hazy notions—perhaps to one fresh from the Examining Board not pleasant ones—of a central authority at Washington, of a Yama enthroned as Secretary of War, and of an exacting Surgeon-General, the young officer who has enjoyed the delightful opportunities of four months' study amid these inspiring surroundings, which teem with reminders of the glories of the corps and of the greatness of his profession, the young officer, I say, must be indeed a muddy-mettled fellow who does not carry away, not alone rich stores of information, but, most precious of all educational gifts, a true ideal of what his life-work should be.

Members of the Graduating Class: Though to you it may not, to me it seems peculiarly appropriate that the Surgeon-General should have asked a civilian to make an address on this occasion. With the strictly military aspects of your future life you have made yourselves familiar; of the merits and demerits of the army as a career for a physician you have in the past four months heard very much; but about all subjects there are some questions which are more freely handled by one who is unhampered by too particular knowledge, and this is my position, I may say my advantage, to-day. For me the Army Medical Department, so far as particulars are concerned, means a library with unsurpassed facilities, the worth of which is doubled by the liberality of its management; a museum in which I have spent some delightful hours; an index-catalogue, which is at my elbow like a dictionary; and the medical history of the late war, particularly the volumes by Woodward and Smart. Further, I have here and there gleaned in my general reading in the history of the profession of this country facts about the corps and its members. I have read the spirited vindication of John Morgan, who may be called the first Surgeon-General, and I am familiar with the names and works of many of your distinguished predecessors who have left their mark in our literature.

But as I write an aspiration of the past occurs, bringing me, it seems, closer to you than any of the points just mentioned, a recollection of the days when the desire of my life was to enter the India Medical Service, a dream of youth, dim now and almost forgotten—a dream of "Vishnu land, what Avatar!"

Speaking, then, from the vantage ground of my ignorance, let me tell you briefly of the opportunities of the life you have chosen. First among your privileges I shall place a feature often spoken of as a hardship, viz., the frequent change from station to station. Permanence of residence, good undoubtedly for the pocket, is not always best for wide mental vision in the physician. You are modern representatives of a professional age long past, of a day when physicians of distinction had no settled homes. You are Cyprid larvæ, unattached, free-swimming, seeing much in many places; not fixed, as we barnacles of civil life, head downward, degenerate descendants of the old professional Cirripeds, who laid under contribution not one, but a score of cities.

Without local ties, independent of the public, in, while not exactly of, our ranks, you will escape many of the anxieties which fret the young physician—the pangs of disprized worth, the years of weary waiting, the uncertainty of the effort; and perhaps those sorer trials inevitable in an art engaging equally heart and head, in which, from the very nature of the occupation, the former is apt—in finer spirits—to be touched with a grievous sensibility. In change, that leaven of life denied to so many, you will find a strong corrective to some of the most unpleasant of the foibles which beset us. Self-satisfaction, a frame of mind widely diffused, is manifest often in greatest intensity where it should be least encouraged, and in individuals and communities is sometimes so active on such slender grounds that the condition is comparable to the delusions of grandeur in the insane. In a nomad life this common infirmity, to the entertainment of which the twin sisters, Use and Wont, lend their ever-ready aid, will scarcely touch you, and for this mercy give thanks. And while you must, as men, entertain many idols of the tribe, you may at least escape this idol of the cave. Enjoying the privilege of wide acquaintance with men of very varied capabilities and training, you can, as spectators of their many crotchets and of their little weaknesses, avoid placing an undue estimate on your own individual powers and position. As Sir Thomas Browne says, it is the "nimbler and conceited heads that never looked a degree beyond their nests that tower and plume themselves on

[1] An address delivered at the closing exercises of the Army Medical School, Washington, D. C., February 28, 1894.

slight attainments," but "heads of capacity and such as are not full with a handful or easy measure of knowledge think they know nothing till they know all."

Per contra, in thus attaining a broader mental platform, you may miss one of the great prizes of the profession—a position in a community reached in length of days by one or two, who, having added to learning, culture, to wisdom, charity, pass the evening of their lives in the hearts of their colleagues and of their kind. No gift of Apollo, not the Surgeon-Generalship, not distinguished position in science, no professorship, however honored, can equal this, this which, as wandering Army Surgeons, you must forego. Fortunate is it for you that the service in one place is never long enough to let the roots strike so deeply as to make the process of transplantation too painful. Myself a peripatetic, I know what it is to bear the scars of partings from comrades and friends, scars which sometimes ache as the memories recur of the days which have flown and of the old familiar faces which have gone.

Another aspect of the life of the Army Surgeon, isolation in some degree from professional colleagues, will influence you in different ways—hurtfully in the more dependent natures, helpfully in those who may have learned that "not from without us, only from within comes, or can ever come, upon us light"—and to such the early years of separation from medical societies and gatherings will prove a useful seed-time for habits of study, and for the cultivation of the self-reliance that forms so important an element in the outfit of the physician. And, after all, the isolation is neither so enduring nor so corroding as might have fallen to your lot in the routine of country practice. In it may be retained, too, some measure of individuality, lost with astonishing rapidity in the city mills that rub our angles down and soon stamp us all alike. In the history of the profession there are grounds for the statement that isolation promotes originality. Some of the most brilliant work has been done by men in extremely limited spheres of action, and during the past hundred years it is surprising how many of the notable achievements have been made by physicians dwelling far from educational centers—Jenner worked out his discovery in a village; McDowell, Long, and Sims were country doctors; Koch was a district physician.

So much depends upon the sort of start that a man makes in his profession that I cannot refrain from again congratulating you on the opportunities enjoyed during the past four months, which have not only added enormously to your capabilities for work, but have familiarized you with life at the heart of the organization of which hereafter you will form part, and doubtless have given you fruitful ideas on the possibilities of your individual development. Naturally each one of you will desire to make the best use of his talents and education, and let me sketch briefly what I think should be your plan of action.

Throw away, in the first place, all ambition beyond that of doing the day's work well. The travellers on the road to success live in the present, heedless of, taking thought for, the morrow, having been able at some time, and in some form or other, to receive into their heart of hearts this maxim of the Sage of Chelsea: Your business is "not to *see* what lies dimly at a distance, but to *do* what lies clearly at hand." Fevered haste is not encouraged in military circles, and if you can adapt your intellectual progress to army rules, making each step in your mental promotion the lawful successor of some other, you will acquire little by little those staying powers without which no man is of much value in the ranks. Your opportunities for study will cover at first a wide field in medicine and surgery, and this diffuseness in your work may be your salvation. In the next five or ten years note with accuracy and care everything that comes within your professional ken. There are, in truth, no specialties in medicine, since to know fully many of the most important diseases a man must be familiar with their manifestations in many organs. Let nothing slip by you; the ordinary humdrum cases of the morning routine may have been accurately described and pictured, but study each one separately as though it were new—so it is so far as your special experience goes; and if the spirit of the student is in you the lesson will be there. Look at the cases not from the standpoint of text-books and monographs, but as so many stepping-stones in the progress of your individual development in the art. This will save you from the pitiable mental attitude of the men who travel the road of practice from Dan to Beersheba, and at every step cry out upon its desolation, its dreariness, and its monotony. With Laurence Sterne, we can afford to pity such, since they know not that the barrenness of which they complain is within themselves, a result of a lack of appreciation of the meaning and method of work.

In the early years of service your advantages will be fully as great as if you had remained in civil life. Faithfulness in the day of small things will insensibly widen your powers, correct your faculties, and in moments of despondency comfort may be derived from a knowledge that some of the best work of the profession has come from men whose clinical field was limited but well-tilled. The important thing is to make the lesson of each case tell on your education. The value of experience is not in seeing much, but in seeing wisely. Experience in the true sense of the term does not come to all with years, or with increasing opportunities. Growth in the acquisition of facts is not necessarily associated with development. Many grow through life mentally as the crystal, by simple accretion, and at fifty possess, to vary the figure, the unicellular mental blastoderm with which they started. The growth which is organic and enduring, is totally different, marked by changes of an unmistakable character. The observations are made with accuracy and care, no pains are spared, nothing is thought a trouble in the investigation of a problem. The facts are looked at in connection with similar ones, their relation to others is studied, and the experience of the recorder is compared with that of others who have worked upon the question. Insensibly, year by year, a man finds that there has been in his mental protoplasm not only growth by assimilation but an actual development, bringing fuller powers of observation, additional capabilities of nutrition, and that increased breadth of view which is of the very essence of wisdom.

As clinical observers, we study the experiments which Nature makes upon our fellow-creatures. These experiments, however, in striking contrast to those of the laboratory, lack exactness, possessing as they do a vari-

ability at once a despair and a delight—the despair of those who look for nothing but fixed laws in an art which is still deep in the sloughs of Empiricism; the delight of those who find in it an expression of a universal law transcending, even scorning, the petty accuracy of test-tube and balance, the law that in man "the measure of all things," mutability, variability, mobility, are the very marrow of his being. The *clientèle* in which you work has, however, more stability, a less extended range of variation than that with which we deal in civil life. In a body of carefully selected active young men, you have a material for study in which the oscillations are less striking, and in which the results of the experiments, *i.e.*, the diseases, have a greater uniformity than in infancy and old age, in the enfeebled and debauched. This adds a value to the studies of army medical officers, who often have made investigations in hygiene, dietetics, and medicine, so trustworthy and thorough that they serve us as a standard of comparison, as a sort of *abscissa* or base-line. Thus you have demonstrated to us, and to the community at large, the possibilities of stamping out smallpox by systematic revaccination; in civil practice we strive to reach the low rate of mortality of army hospitals in the treatment of typhoid fever and of pneumonia. Many of the most important facts relating to etiology and symptomatology have come from camp or barrack. I often think that army surgeons scarcely appreciate that in their work they may follow the natural history of a disease under the most favorable circumstances; the experiments are more ideal, the conditions less disturbing than those which prevail either in family practice or in the routine of the general hospital. Many of the common disorders can be tracked from inception to close, as can be done in no other line of medical work, and the facilities for the continuous study of certain affections are unequalled. This, which is a point to be appreciated in the intrinsic education of which I spoke, gives you a decided advantage over your less favored brethren.

Your extraordinary range of observation, from the Florida Keys to Montana, from Maine to Southern California, affords unequalled facilities for the study of many of the vexed problems in medicine—facilities, indeed, which in the diversity of morbid conditions to be studied are equalled in no position in civil live. Let me here mention a few of the subjects that may profitably engage your attention. No question is of more importance at present than the settlement, definitely, of the varieties of fever in the West and South. The studies of Baumgarten in St. Louis, and of Guitéras and others in the Southern States, suggest the possibility that in addition to typhoid fever and malaria—the common affections—there are other fevers the symptomatology and morbid anatomy of which still require careful elucidation. In this you will be walking in the footsteps of notable predecessors in the corps, and in the exhaustive works of Woodward and Smart, to which I have already alluded, and which are always available, you will find a basis from which you may start your personal observations. More particularly in this direction do we need careful anatomic investigation, since the symptomatology of certain of the affections in question has much in common with that of the ordinary continued fevers of the North. I may call your attention to the satisfactory settlement of the nature of mountain fever by army surgeons, and need hardly add that the specimens contributed by Hoff and by Girard to this museum demonstrate conclusively that it is in reality typhoid fever.

In the Southern posts malaria with its protean manifestations presents still many interesting problems for solution, and you will leave this school better equipped than any of your predecessors for the study and differentiation of its less known varieties. With positive knowledge as to the etiology, and a practical familiarity with methods of blood-examination, you can do much in many localities to give to malaria a more definite position than it at present occupies in the profession, and can offer in doubtful cases the positive and satisfactory test of the microscope. The hematuria of the South requires to be studied anew—the filarial cases separated from the malarial, and, most important of all, the relation of quinin to hematuria positively settled.

In the more distant posts, where, so far as the soldier is concerned, your opportunities for study may be limited, you may add greatly to our knowledge of the disorders prevalent among the Indians. More particularly do we need additional information as to the frequency of tuberculosis among them, and its clinical history. One of your number, Dr. Edwards, has already furnished admirable statistics upon this point, but the field is still open and much remains to be done. In this connection, too, you may be able to carry saving knowledge upon the etiology of the disease, and enforce regulations for its prevention. You have only to turn to the Index-catalogue to see how scanty in reality are the facts in the nosology of the North American Indian.

At many posts there will be presented to you the interesting effects of altitude, with problems of the greatest physiologic importance. An excellent piece of work may be done upon its influence upon the red blood-corpuscles, in determining whether, as has been maintained, there is an increase numerically per cubic millimeter, so long as the individual remains in the more rarefied atmosphere. Points remain to be settled also upon the effects of altitude upon the chest-capacity, the chest-measurement, and the heart, and our knowledge is still lacking on questions relating to the influence of high altitudes upon many of the ordinary diseases.

To one of you, perhaps, another peculiarly American disease—milk-sickness—may reveal its secret. Our knowledge of its etiology has not been materially increased since the early papers on the subject, which so well described its symptomatology.

These are but a few of the questions suggesting themselves to my mind, to which, as chance affords, you could direct your attention. In a ten or fifteen years' service, travelling with seeing eyes and hearing ears, and carefully-kept note-books, just think what a storehouse of clinical material may be at the command of any one of you—material not only valuable in itself to the profession, but of infinite value to you personally in its acquisition, rendering you painstaking and accurate, and giving you, year by year, an increasing experience of the sort to which I have already more than once referred.

In what I have said hitherto I have dwelt chiefly on your personal development, and on the direction in which your activities might be engaged, but while you are thus laying the foundation of an education in all that relates

to the technical side of the profession, there are other duties which call for a word or two. In the communities to which you may be sent do not forget that, though army officers, you owe allegiance to an honorable profession, to the members of which you are linked by ties of a most binding character. In situations in which the advantages of a more critical training give you a measure of superiority over your confrères in civil life, let it not be apparent in your demeanor, but so order yourselves that in all things you may appear to receive, not to grant favors. There are regions, *in partibus infidelium*, to which you will go as missionaries, carrying the gospel of loyalty to truth in the science and in the art of medicine, and your lives of devotion may prove to many a stimulating example. You cannot afford to stand aloof from your professional colleagues in any place. Join their associations, mingle in their meetings, giving of the best of your talents, gathering here, scattering there; but everywhere showing that you are at all times faithful students, as willing to teach as to be taught. Shun as most pernicious that frame of mind, too often, I fear, seen in physicians, which assumes an air of superiority, and limits as worthy of your communion only those with satisfactory collegiate or sartorial credentials. The passports to your fellowship should be honesty of purpose and a devotion to the highest interests of our profession, and these you will find widely diffused, sometimes apparent only when you get beneath the crust of a rough exterior.

If I have laid stress upon the more strictly professional aspects of your career it has been with a purpose. I believe the arrangements in the department are such that, with habits of ordinary diligence, each one of you may attain not only a high grade of personal development, but may become an important contributor in the advancement of our art. I have said nothing of the pursuit of the sciences cognate to medicine, of botany, zoölogy, geology, ethnology, and archeology. In every one of these, so fascinating in themselves, it is true that army medical officers have risen to distinction, but I claim that your first duty is to medicine, which should have your best services and your loyal devotion. Not, too, in the perfunctory discharge of the daily routine, but in zealous endeavor to keep pace with, and to aid in, the progress of knowledge. In this way you will best serve the department, the profession, and the public.

Generalities, of the kind in which I have been indulging, though appropriate to the occasion, are close kin, I fear, to the fancies fond, that vanish like the gay motes which float for a moment in the sunbeams of our mind. But I would fain leave with you, in closing, something of a more enduring kind—a picture that for me has always had a singular attraction, the picture of a man who, amid circumstances the most unfavorable, saw his opportunity and was quick to "grasp the skirts of happy chance." Far away in the northern wilds, where the waters of Lake Michigan and Lake Huron unite, stands the fort of Michilimackinac, rich in the memories of Indian and *voyageur*, one of the four important posts in the upper lakes in the days when the Rose and the Fleur-de-lys strove for the mastery of the Western world. Here was the scene of Marquette's mission, and here beneath the chapel of St. Ignace they laid his bones to rest. Here the intrepid La Salle, the brave Tonty, and the resolute Du Luht had halted in their wild wanderings. Its palisades and bastions had echoed the war-whoops of Ojibwas and Ottawas, of Hurons and Iroquois, and had been the scene of bloody massacres and of hard-fought fights. At the conclusion of the war of 1812, after two centuries of struggle, peace settled at last upon the old fort, and early in her reign celebrated one of the most famous of her minor victories, one which carried the high-sounding name of Michilimackinac far and wide, and into circles where Marquette, Du Luht, and La Salle were unknown. Here, in 1820, was assigned to duty at the fort, which had been continued in use to keep the Indians in check, Surgeon William Beaumont, then a young man in the prime of life. On the 22d of June, 1822, the accidental discharge of a musket made St. Martin, a *voyageur*, one of the most famous subjects in the history of physiology, for the wound laid open his stomach, and he recovered with a permanent gastric fistula of an exceptionally favorable kind. Beaumont was not slow to see the extraordinary possibilities that were before him. Early in the second decade of the century the process of gastric digestion was believed to be due to direct mechanical maceration or to the action of a vital principle, and though the idea of a solvent juice had long been entertained, the whole question was *sub judice*. The series of studies made by Beaumont on St. Martin settled forever the existence of a solvent fluid capable of acting on food outside as well as within the body, and in addition enriched our knowledge of the processes of digestion by new observations on the movements of the stomach, the temperature of the interior of the body, and the digestibility of the various articles of food. The results of his work were published in 1833, in an octavo volume of less than 300 pages.[1] In looking through it one cannot but recognize that it is the source of a very large part of the current statements about digestion; but apart altogether from the value of the facts, there are qualities about the work which make it a model of its kind, and on every page is revealed the character of the man. From the first experiment, dated August 1, 1825, to the last, dated November 1, 1833, the observations are made with accuracy and care, and noted in plain, terse language. A remarkable feature was the persistence with which for eight years Beaumont pursued the subject, except during two intervals when St. Martin escaped to his relatives in Lower Canada. On one occasion Beaumont brought him a distance of two thousand miles to Fort Crawford, on the upper Mississippi, where, in 1829, the second series of experiments was made. The third series was conducted in Washington, in 1832; and the fourth at Plattsburg, in 1833. The determination to sift the question thoroughly, to keep at it persistently until the truth was reached, is shown in every one of the 238 experiments which he has recorded.

The opportunity presented itself, the observer had the necessary mental equipment and the needed store of endurance to carry to a successful termination a long and laborious research. William Beaumont is indeed a bright example in the annals of the Army Medical Department, and there is no name on its roll more

[1] "Experiments and Observations on the Gastric Juice and the Physiology of Digestion," by William Beaumont, M.D., Surgeon in the United States Army, Plattsburg, 1833.

deserving to live in the memory of the profession of this country.

And in closing let me express the wish that each one of you, in all your works begun, continued, and ended, may be able to say with him: "Truth, like beauty, 'when unadorned is adorned the most,' and in prosecuting experiments and inquiries I believe I have been guided by its light."

CLINICAL LECTURE.

PHIMOSIS AND THE CONDITIONS THAT IT COMPLICATES IN THE ADULT.[1]

By WILLIAM P. MUNN, M.D.,
of Denver, Col.;
Professor of Genito-Urinary Diseases and Clinical Surgery in the University of Denver; Genito-Urinary Surgeon to the Arapahoe County Hospital, and Consulting Surgeon to St. Luke's Hospital.

The patients shown you to-day will illustrate several phases of that rather common condition, phimosis, and the diseased conditions that are complicated and rendered more difficult of treatment by the presence of phimosis. First, let me direct your attention to these three cases circumcised some time ago and presenting resulting conditions of varying perfection. These men had all of them redundant foreskins, and each of them was the victim of mixed venereal infection; two contracted the initial lesion of syphilis and the simple venereal ulcer or chancroid at or about the same time; one contracted syphilis and gonorrhea at the same time.

In this first patient, Peter M., the sore, then recognized as chancroid only, was situated upon the prepuce just at the junction of the skin and mucous membrane, and was not only difficult to treat but was refractory to treatment. It was apparent that removal of the foreskin was necessary, and if neatly and cleanly done so that the operation-wound should not be contaminated, would lessen the difficulty of treatment by removing the sore at the same time. This was done and an eminently satisfactory result obtained. The fine linear scar can now hardly be seen, there is no thickening of the mucous membrane, and the very slight edema near the frenum will disappear in a few weeks. We have here, then, what may very properly be called an ideal result of the operation of circumcision. In the patient's left groin you observe the depressed, puckered scar left by the wound made in excising the bubo which occurred there as an accompaniment of his chancroid. The incision healed almost entirely by first intention. In the time that has elapsed since the operation, mucous patches in the mouth and other secondary manifestations of syphilis have made their appearance, and the man is now taking mercury and potassium iodid in free dosage.

The next man, you will remember, had secondary manifestations of syphilis and a free gonorrheal discharge. On account of his elongated prepuce it was not only difficult to effectively treat his gonorrhea, but the retained secretion excoriated the mucous membrane of the glans and of the prepuce. With this patient the circumcision was done by the method of first slitting the foreskin with scissors to a point back of the glans, then trimming off the corners of the flaps, and suturing the skin and mucous membrane. The result is not so perfect as in the first patient, but may still be considered satisfactory. In a few months the swelling and infiltration will disappear and there will be little evidence left of operative procedure.

This third patient I wish to place in contrast with the two already shown. He has been subjected to a simple incision of the prepuce in order to facilitate treatment of a mixed sore located on the frenum. As you see, the real object of the incision was not attained, for the long and flabby lower flap of the prepuce has remained in continuous contact with the glans, and the chancroidal process, which was probably serpiginous, pursued its uninterrupted course and has quite destroyed the frenum. This is an excellent example of a bad result due to an incomplete operation. But the present condition is not such as to demand further immediate operation, as the chancroid is now undergoing cicatrization and will soon be quite well. Some points in reference to this man's mixed infection are of sufficient importance to justify a slight divergence from our main subject for their brief consideration. As he opens his mouth you can see the well-marked mucous patches becoming confluent upon the palate just to the right of the uvula; his hair is also coming out, the spots upon the skin are very apparent, and as I now have him lean over and spread apart the buttocks so as to expose the anus you can observe characteristic mucous patches upon the anal mucous membrane. These are incontrovertible evidences of the second stage of syphilis. They are of especial importance in connection with the history given by the patient. Before entering the hospital he had been under treatment by an irregular syphilis-specialist who had so dosed him with mercury on the appearance of the mixed sore upon his penis, that he was thoroughly ptyalized before the appearance of the secondary manifestations. Now note that the saturation of the system with mercury did not prevent the occurrence of the secondary signs. This remedy antagonizes the effects of syphilis, but does not prevent the action of the syphilitic poison or germ. The medication was ill advised because at the time it was given the disease was still a local process and there were no constitutional manifestations to be met by the administration of mercury as a constitutional remedy. The result was the development of ptyalism without any arrest of the onward progress of the disease.

To return to our original subject, phimosis and its relief by circumcision. The man who has just been anesthetized is over seventy years of age. He has an extremely long and very tight foreskin, and in addition you will notice that there is present a free, purulent discharge from the urethra. This discharge is a typical gonorrheal flow, and he gives a history of venereal exposure some ten or twelve days prior to the inception of the discharge. The fact deserves emphasis, that no age is exempt from gonorrhea if exposure occurs. It is usually a disease of young adult life, but it may occur at any age, as I have before seen it in men of about the same age as this patient, and also in little children. Last year we had in the hospital a girl four years old with a gonorrheal vulvitis due to wearing clothes soiled with the discharge from an older patient; a boy five years old who

[1] A Clinical Lecture delivered at the Arapahoe County Hospital, January 30, 1894.

had acquired it in some unknown manner, and a boy eight years old who had gotten it by attempted sexual intercourse with an older girl.

This man's prepuce is so long that it has thus far absolutely prevented not only treatment of the urethra but has rendered cleansing of the fossa back of the glans practically impossible. Immediate circumcision is the only proper treatment for this condition. Dr. Stover, the surgical resident, will perform the operation. Instead of following any of the elaborate and somewhat fantastic methods that have been devised, we follow a method which is simplicity itself and which gives results as nearly ideal as any of which I know. The end of the prepuce is held either between the thumb and forefinger of the left hand or grasped in a forceps held in the left hand. With scissors curved on the flat, the redundant foreskin is then removed at one stroke. Danger of wounding the glans penis by this method amounts to nothing, for the glans glides back from the scissors so quickly and easily that it would be impossible to nip it if the effort were made. As the skin of the sheath retracts the mucous membrane is seen still encircling the glans. Before proceeding any further it is well to arrest all hemorrhage. Firm pressure with a gauze sponge will frequently suffice, but if the artery of the frenum bleeds freely, as in this case, it is seized with artery-forceps and twisted with five or six full turns of the forceps. The mucous membrane is now slit backward on the dorsum of the glans nearly to the corona glandis and the flaps rolled back. There is one precaution to be taken at this point, and that is to avoid entering the scissors-blade in the meatus. Little likely to occur as this seems to be, yet it has occurred, and careless operators have clipped through the glans as well as the preputial mucous membrane. The corners of the reflected mucous flaps are now trimmed off with the scissors, and, after thoroughly cleansing the glans and removing accumulated smegma from behind the corona, the mucous membrane and the skin are sutured with interrupted silkworm-gut sutures. Ten stitches are inserted in this case. The dressing is a simple antiseptic one, powdered iodoform being rubbed into the wound-surface; several layers of iodoform-gauze are applied and held in place by a rubber band. The stitches may be removed in a week, and I anticipate complete primary union.

Our next patient is a younger man, about twenty-five years old. The foreskin is long and lax—no tightness whatever. You can see no sore and there is no discharge present, but as he retracts the foreskin there appear some of the results of irritation from the continuous moisture of retained secretions. The inner surface of the prepuce, and the glans penis as well, are covered with mushroom-like growths varying from an eighth to a half inch in diameter. These vegetations are venereal warts, and this man has about as large a crop of them as you will often see. He has been in the hospital before and had a number of warts clipped off or burned with acids, but there is very prompt recurrence because the predisposing causes, this elongated prepuce and his uncleanly habits, still persist. He has, as you see, no specific venereal disease, and these papillomata are but the results of long-continued irritation and maceration of the mucous membrane. These growths were not apparent until the prepuce was retracted, yet there is a large mass of them demanding immediate interference. This emphasizes the necessity of making a thorough examination of each case by retracting or causing to be retracted the redundant prepuce. Until this is done it is impossible to know or even guess what may be concealed; perhaps such growths as these are, perhaps a malignant growth, an initial lesion, a chancroid, an injury, a mass of retained secretions, or even a calculus. I remember especially the case of a man who was in the medical ward last year, with obscure febrile symptoms. After several days he incidentally gave a history of passing blood with his urine, and it was presumed that it came from his bladder or kidney. On examining him I found that it came either from the penis or the urethra, and at first glance I thought he might have introduced some foreign body into the urethra, but upon retraction of a long and rather tight prepuce there was exposed back of the glans a serpiginous chancroid nearly an inch and a half in its greatest diameter which had eaten into the body of the penis and opened the artery of the dorsum. A few days' further delay in discovering the sore would probably have resulted in entire loss of the glans penis.

The treatment of the present case will be removal of the warts and of the prepuce, and I will ask Dr. Mack, the chief resident, to perform the operation. We will employ cocain-anesthesia in this case. As a preliminary the penis is first rendered bloodless by pressure, after having been wrapped with bichlorid gauze. A rubber band is now placed at the root of the penis and serves to control the return circulation. We employ a ten per cent. solution of cocain and inject two or three drops upon the dorsum, upon each side and near the frenum; in all ten drops are used, representing about one grain of cocain. As the warts are removed, their bases are freely touched with Monsel's solution. The prepuce is removed in the same manner as in the former case, and the artery of the frenum requires torsion here also. Suturing and dressing are the same as before.

The result of continued neglect of the benign papillomata which occur in patients like this may be the conversion of a benign into a malignant process. Almost all cases of epithelioma of the penis occur in patients having just such long foreskins, and the continuous irritation of the retained secretions has been the active factor in causing malignant development.

Here comes the last patient for to-day's clinic. His penis and what is left of his prepuce present a peculiar appearance. He has been circumcised before, but whoever operated upon him failed to break up the adhesions between the glans and the prepuce, and as a result only the end of the glans is visible. All of the movable mucous membrane of the prepuce has also been removed, and so we have the skin almost directly united to the glans, with only the slightest amount of retraction possible. I shall endeavor to improve the present condition, although it is quite impossible to secure a perfect result. The patient is now under chloroform, and I dissect with scissors between the prepuce and the glans until the corona is reached and exposed as fully as possible. In the same careful way, by a circular dissection, the thick, bulging scar-tissue left by the former operation is removed, and what little mucous membrane has been

raised from the surface of the glans by dissection is carefully sutured to the edge of the skin. This is not, by any means, a beautiful result, but it promises to be a great improvement over his former condition both as to the appearance of the member and in increasing the patient's comfort.

In conclusion, gentlemen, it may seem to you that we have given a great deal of time to a trivial and somewhat disagreeable subject. I am aware that abdominal and cranial operations are more attractive to both students and practising physicians than are minor genito-urinary operations, but I am convinced that you will all have to perform such operations as circumcision perhaps many times before you undertake the major operations. There is often more of reputation and of profit for the young physician in a neatly done circumcision, with a good result, than in all the major surgery that comes to him.

CLINICAL MEMORANDA.

DERMOID CYST OF THE OVARY SIMULATING APPENDICITIS.

By M. ROSENHEIMER, M.D.,
of Milwaukee, Wis.

Mrs. A. B., of Goodell, Iowa, aged twenty-six years, of American parentage, came to this city to pay a visit to her parents, who reside here, after a week's sojourn at the World's Fair. When she left her home in Iowa she was in her usual health. She arrived in this city on the 3d of September last. On the 14th she first began to feel ill, with pain in the abdomen, but as she was menstruating at the time and usually suffered some pain during her periods, she attributed the pain to this cause. The pain, however, increased and medical advice was sought. The physician called relieved her by the use of anodynes, and for a short time she felt comfortable. On the evening of the 17th of September I was requested to see her. I found the patient, a small woman, greatly emaciated, complaining of severe pain in her abdomen. She felt constantly nauseated, and vomited whenever anything was taken into the stomach. On examination I found the muscles of the abdomen tensely contracted, the thighs flexed, and the face conveying an impression of intense suffering.

The seat of greatest tenderness was in the right iliac region, extending toward the median line, and a slight elevation was discernible. There was flatness on percussion, extending from the right iliac region to the linea alba. Her tongue was covered with a brownish fur; the pulse was 108; the temparature was not taken. The bowels had not moved since the 14th, and several injections of soap-water, given just previous to my seeing her, brought away very little. I gave the patient's friends to understand that she was seriously ill, and was apparently suffering from appendicitis, though possibly from some other form of intestinal obstruction.

Thinking the condition might possibly be one of fecal impaction, I prescribed several doses of the mild chlorid of mercury and gave directions as to its administration. The family requested that I call again the following day. At 6 o'clock A.M., on the 18th, the patient's father called at my residence and requested me to come at once. On inquiry I found that the woman had retained a part of the calomel and that she had had a passage from the bowels. She still vomited and the pain was not decreased. On local examination I found the elevation in the right iliac region more marked than on the previous evening, and thought I could detect fluctuation. She had not rested any during the night. I made a digital examination per rectum and vagina, and detected a tumor of a doughy consistency in the right iliac region, but on account of the great pain conjoined manipulation was impossible. I advised counsel and called in Drs. Nielson and Hoyer. On consultation an operation was considered imperative by all and proposed to the friends. The relatives readily consented, and on stating the case openly to the patient, after a little deliberation she requested the operation. She was removed to the hospital, and at 12.30 I operated, assisted by Drs. Nielson and Hoyer. An incision was made over the highest point of the elevation, about an inch and a half within Poupart's ligament and parallel with it. On opening the peritoneum about a half-pint of a dark fluid escaped and a tumor presented. After a closer investigation and finding no adhesions, it was decided to remove the mass. The incision was enlarged, and after opening the sac and evacuating some of the contents, a bundle of curled hair about the size of a small orange appeared, and betrayed the character of the growth. With some difficulty it was lifted out, and it was then discovered that the pedicle was twisted, and that the tumor had the appearance of beginning gangrene. The pedicle being securely ligated and cut, the abdomen was freely irrigated with several gallons of sterilized water and the wound closed, with the exception of its lower angle, in which a large rubber drain, wrapped with iodoform-gauze, was introduced. A thick antiseptic dressing was applied and the patient put to bed. She reacted well, and, with the exception of great thirst, felt very comfortable. She was allowed to drink hot water, but took nothing else for the first twenty-four hours. During the following night her temperature became subnormal and her pulse very rapid and feeble, but it responded readily to a nutrient enema and hypodermatics of brandy and strychnin. She did not feel much nauseated and never vomited after the operation. Her bowels moved freely after a glycerin enema on the third day, and spontaneously afterward. The highest temperature attained was 99.6°, on the second day. The wound healed kindly, the drain being removed after twenty-four hours and the opening allowed to granulate. Then followed a rapid and complete recovery, and the woman returned to her home in Iowa five weeks later.

In a letter since received, her husband states that she felt better than ever and was gaining in strength and flesh.

The cyst contained about a pint of a thick greasy fluid, a bundle of hair, and imbedded in its wall was an adult incisor tooth, and a bone resembling one of the long bones of a fetus.

The Ohio State Medical Society will hold its annual session at Zanesville, Ohio, May 16th, 17th, 18th. Dr. N. P. Dandridge, of Cincinnati, is the President, and Dr. Thomas Hubbard, of Toledo, Secretary.

TYPHOID FEVER COMPLICATED BY TWIN ABORTION; RECOVERY.[1]

German Hospital, Philadelphia.

SERVICE OF ADAM TRAU, M.D.

[Reported by ARTHUR J. PATEK, M.D., Resident Physician.]

MRS. M. W., twenty-nine years of age, was admitted to the hospital during the acme of a frank attack of typhoid fever. She was found to be four months pregnant. Fearing a possible abortion, the routine bath-treatment was at first withheld, and for three days the temperature combated with spongings. This, however, proved unsatisfactory, and on the third day the bath-treatment was inaugurated. Thirty baths only were given, the temperature falling on the eighth day, but maintaining a fluctuating character about the normal line for two weeks. Again it rose, fluctuating between 104° F. and normal, and being quite septic in type. The possibility of infection from a dead and macerated fetus was considered, but not long entertained, because of the absence of foul discharges and of any other symptom of a septic condition. On the forty-first day of the fever the patient fell into labor. Though the pains were of but moderate severity, labor progressed nicely, and in three hours' time the patient was delivered of five-month twin fetuses—dead, but otherwise normal. Both placentæ came away entire and there was but an inappreciable amount of hemorrhage. The fever remained uninfluenced by this complication, nor did the patient suffer any ill effects. The temperature remained as before, of a septic character, for one week after the abortion, and then declined to the normal, remaining so until the woman was discharged.

The fever-curve, when viewed as a whole, gives the impression of a distinct relapse in the fourth week of the disease. The temperature is fluctuating, it is true, but there is a distinct rise, more or less gradual, a stadium during which the abortion took place, and a defervescence.

There are two points of interest in this case worthy of special mention: First, that a pregnant uterus should have remained quiescent during five weeks of almost continuous fever—104.4° being the highest recorded; secondly, that there should have been a temperature bordering on the septic type for three weeks continuously before the abortion and one week thereafter, the contents of the womb being throughout in an apparently healthy state. It was evident, therefore, that the fever was but slightly, if at all, affected by the state of pregnancy, but is to be attributed almost entirely to the typhoidal condition.

As a most interesting feature in the case may be mentioned the fact that delivery of both fetuses was accomplished without rupture of either amniotic sac, a circumstance which is certainly of rather rare occurrence.

The Medical Association of Georgia will hold its Forty-fifth Annual Session at Atlanta, Ga., on April 18th, 19th, and 20th. Dr. W. H. Elliott, of Savannah, is President, and Dr. Dan H. Howell, of Atlanta, Secretary.

---

PATHOLOGIC NOTE.

DIFFUSE COAGULATION-NECROSIS IN THE SPLEEN FOLLOWING THROMBOSIS IN TYPHOID FEVER AND PNEUMONIA.

BY LUDVIG HEKTOEN, M.D.,
PATHOLOGIST TO THE COOK COUNTY HOSPITAL, CHICAGO.

As is generally well known, areas of coagulation-necrosis in the shape of characteristic anemic or hemorrhagic infarcts are found quite frequently in the spleen after death from typhoid fever. The areas of necrosis are due either to a local thrombosis, to embolism, or to the intensity of the acute inflammatory changes that occur.

Inasmuch as an instance of general thrombosis throughout the spleen and a consecutive diffuse necrosis has not to my knowledge come under observation as far as can be learned from the literature at my disposal, at least not in the early stage, it was deemed advisable to place upon record a description of such a specimen even though the observations are in many respects exceedingly imperfect.

The patient was a man, thirty-three years old, acting as a guard at the World's Fair. He passed through an attack of lung-fever in 1881 and of typhoid fever in 1885. After having been three months in Chicago, he began to suffer from headache, anorexia, general malaise, and occasional epistaxis. Ten days after the first symptoms made their appearance, on June 8, 1893, he was admitted to the Cook County Hospital in a typical typhoid condition, with roseola, increased splenic dulness, etc. He passed through an attack of ordinary severity, the pulse varying from 70 to 100, the temperature occasionally reaching 104° during the fastigium, respiration being from 20 to 30. The treatment was entirely routine—milk-diet, sponge-baths, and salol internally. The intestinal symptoms were never prominent. The man was thought to be on the way to rapid convalescence, but on June 30th there was found an area of dulness and loss of respiratory murmur over the right infra-clavicular region, the lungs being normal elsewhere. On July 3d there was noted hemoptysis, with quite distinct physical signs of a small cavity in the right upper lobe anteriorly; elsewhere in the lungs were sonorous and mucous râles; the general condition was bad. On the 8th there were found small hemorrhages under the skin; the condition in the lungs was practically unchanged. Death occurred on July 11th.

Anatomic diagnosis: Typhoid ulceration of Peyer's patches; mesenteric adenitis; fibrinous pneumonia with softening in the right upper lobe; broncho-pneumonia; intra-splenic thrombosis and diffuse coagulation-necrosis.

The post-mortem examination, made forty-eight hours after death, showed that the body was quite well nourished, five feet eight inches in length. Rigor was fairly well marked; the usual livores mortis were present. The body-cavities were empty and the lining membranes smooth and shining, except for some soft adhesions about the spleen and the adjacent organs, and also over the upper lobe of the right lung. The mesenteric glands were large. The heart weighed 270 grams. There were no endocardial changes; the myocardium was quite firm and the coronary vessels were normal. In the left lung were a few broncho-pneumonic areas as large as a dime, con-

fined entirely within the upper lobe; the tissue in these foci was grayish-red and granular; there were no evidences of miliary tubercles at their periphery. The upper lobe of the right lung contained a cavity as large as a small orange, partly filled with softened, granular material; the tissue immediately about this cavity was grayish and merged imperceptibly into the semi-solid necrotic contents on the one hand, and into the red, solid lung-parenchyma on the other, the principal part of the lobe being occupied by this cavity and the surrounding gray and red solid tissue. No tuberculous masses, old or recent, could be found in any part of the lungs; the glands at the root of the lungs were not caseous. In the lower lobes of both lungs there was considerable mucopus in the bronchi. Sections of the soft borders of the cavity in the right upper lobe, made with the freezing microtome, showed an intense round-cell infiltration, with foci of disintegration, and the more solid tissue showed infiltration into the alveolar walls and fibrinous exudation into the air-cells; frozen sections from the solid areas in the left lung showed uniform infiltration and inflammatory exudation into the air-spaces. Hardened sections and cover-slip smears stained in various ways did not show any tubercle bacilli, but a large number of various kinds of cocci and bacilli. Unfortunately no cultivation-experiments were made. The spleen will be described last. The kidneys were a little increased in size. The cortical markings were indistinct and the cortex appeared yellowish. The liver and the bile-passages were negative to naked-eye examination. The stomach showed only slight acute catarrhal changes. The mucous surface of the ileum showed fifty-six oblong ulcers, corresponding to the location of Peyer's patches; the borders were smooth and in the lower parts of the ileum the floor appeared like granulation-tissue, while in the uppermost ulcers it was composed of the uncovered muscular coat; in all of the ulcers the borders were smooth, the sloughs all discharged, and consequently they were regarded as in the process of cicatrization. Particular attention was given to the condition of the serous coat over the ulcers, with respect to the presence of tubercles, but none was found either here or in the margins of the ulcers. The pancreas appeared normal and there was nothing pathologic found in the cranial cavity.

The spleen measured 14 x 9 x 5 cm. and weighed 250 grams. The surface was covered here and there with small shreds from the torn adhesions between the spleen, the diaphragm, the end of the left lobe of the liver, and the abdominal wall; close inspection showed the capsule to be overspread with a thin, fibrinous layer that could be removed piecemeal very easily; in color the external surface showed a most peculiar, fine mottling of gray, yellow, and light-red. The consistence of the spleen was like that of a firm, normal liver, and the capsule was as tense as it well could be. On the cut surface it was noted at once that every visible vessel was thrombotic, *i. e.*, filled with a firm, granular, light-red, adherent blood-clot; it is possible that the arteries were not so much involved as the veins; at the hilus each large branch of the splenic vein was thrombotic; but the vein itself was free and smooth, and this was also true of the splenic artery and its larger branches. The cut surface presented all over, to a certain extent, the characteristic appearance of anemic and hemorrhagic splenic infarcts; the color was, however, variable, showing mostly shades of light-red and yellowish-red, with a number of rather minute, homogeneous, irregular, and little depressed areas of dark-gray; with the exception of these homogeneous, dark-gray, apparently normal areas the splenic parenchyma was distinctly and markedly but finely granular, and, as already stated, very solid, though easily friable. The Malpighian bodies and the pulp were nowhere distinguishable; there were no foci of softening and suppuration.

The microscopic examination of the spleen showed in general the following: The majority of the vessels and the vascular spaces are filled with fibrinous thrombi; it is not possible to recognize the vessel-walls sufficiently well to establish definitely any inflammatory changes. The principal part of every section consists of diffusely stained areas, made up of irregular masses, large and small, without any visible nuclei, even though nuclear staining methods are employed; among these masses there passes a fine network of diffusely-stained material, and there are also observed normal and degenerate red blood-corpuscles, but they vary greatly in number in the various fields. These areas of necrosis contain every now and then small foci of tissue which retain to a certain extent the normal spleen-structure, but in nearly all are evidences of necrosis in the shape of homogeneous or granular, diffusely-stained, irregular masses; in these last-described areas are often found dense collections of deeply-stained, sharply-outlined, round nuclei. The distinction between the pulp and the Malpighian bodies cannot be made out in the areas of total necrosis. There are no foci of softening or purulent disintegration. Stains for microörganisms show here and there rather long and thick bacilli.

From the gross and microscopic appearances of this spleen it is quite likely that the extensive thrombosis was primary, and that it occurred simultaneously and to an equal degree in all parts of the organ; the thrombosis did not start in an embolic occlusion, because characteristic wedge-shaped embolic infarcts are not demonstrable in this spleen.

As a consequence of this practically complete thrombosis of all the splenic vessels, the splenic tissue underwent a nearly general diffuse necrosis in the form of coagulation-necrosis, only small foci of tissue retaining its normal structure to a recognizable degree. Perisplenic inflammatory changes also developed.

It is much regretted that a bacteriologic examination could not be carried out fully.

It is not possible to say in what exact manner this unusually extensive and uniform thrombosis was brought about, whether it was marantic, which seems very likely indeed, or due to the degree of splenitis present at the height of the attack of enteric fever, or due to a secondary mixed infection.

COLUMBUS MEMORIAL BUILDING.

MEDICAL PROGRESS.

Excision of Larynx, Hyoid Bone, and Five Rings of Trachea for Malignant Disease.—MACDONALD (*British Medical Journal*, No. 1722, p. 1423) has reported the case of a man, thirty-nine years old, suffering from intense

dyspnea and dysphagia, due to a cartilage-like tumor springing from the larynx and diagnosticated myxosarcoma. Breathlessness had been present for six months, and evidences of laryngeal irritation for more than three years. The dyspnea had progressively increased in intensity, and kept the patient in a state of constant fear of suffocation. From the exterior the larynx and the neoplasm together appeared to be the size of a large orange. The growth spread laterally and up and down, as if the whole front of the neck were a solid mass. The ordinary stomach-tube passed with great difficulty down the esophagus, and it could not be determined whether the esophagus was involved or not. The walls of the larynx were so compressed, and breathing was so difficult, that little could be learned on laryngoscopic examination. The general health appeared good. It was decided to perform a preliminary tracheotomy, to be followed, if possible, by a removal of the mass. Ten days after the performance of a low tracheotomy the mass was incised and found to be almost extra-laryngeal, but involving the thryoid cartilage, the hyoid bone, the upper part of the trachea, and the whole of the soft parts surrounding these structures in front to the level of the skin. The pharynx was slightly involved, but the esophagus seemed to be free. A median incision was made in the whole length of the tumor, and two lateral incisions following the hyoid bone as far as the carotids would permit. The mass was now dissected out from below upward. The hemorrhage was profuse, but principally from the upper portion of the thyroid gland. On arriving at the part around the epiglottis and the hyoid bone, it was found impossible to avoid opening into the pharynx. A strong effort was made to save the epiglottis, but immediately below it the pharynx was opened from side to side. This large gap was carefully sutured over a rectal bougie, and finally fixed to the structures in front. The external wound was left open to facilitate drainage and to avoid the troublesome burrowing of pus that is likely to follow operations in the neighborhood of the trachea. The patient made an excellent recovery. The wounded pharynx gave no trouble, nor was there any difficulty in swallowing after the second day. After the lapse of three months an opening into the mouth was established, and the wound in the pharynx was closed. At first articulation could be better performed without instrumental aid, the epiglottis seeming to take the place of the natural larynx, but subsequently the man became adept in the use of an artificial larynx.

Successful Operation for Spina Bifida with Meningocele.—Stone (*Omaha Clinic*, vol. vi, No. 10, p. 438) has reported the case of an infant that presented a spina bifida in the lower lumbar region and a meningocele just in front of the left parietal eminence. There were no evidences of spinal irritation, and the action of the sphincters was preserved. For a week after birth no material change was noticed in either of the tumors, except that they became more full and tense when the child cried or worried, and relaxed during tranquillity. At this time, however, the meningocele began to diminish in size, while the spina bifida increased in size. The child meanwhile thrived and seemed to suffer no inconvenience from the presence of the two lesions. At the end of two months the cranial opening had closed, leaving only a slight elevated thickening of the bone at the site of the previous fissure. The spina bifida, on the other hand, continued to increase in size. In view of these conditions a portion of the fluid was withdrawn, and a dram of a solution of iodin, 10 grains, potassium iodid, 30 grains, glycerin, 1 ounce, was injected into the sac, and the child kept upon its back for some time. The injection was followed by marked prostration, together with loss of appetite and extreme irritability for several days, and apparent general muscular soreness. The tumor soon resumed its previous size and continued to grow larger. Twelve days later about half of the contents of the tumor were withdrawn by aspiration, and a compress adjusted. The walls of the cyst began to yield and fluid to escape. A radical operation was now decided upon. The child was at the time eighty-four days old. The infant was placed upon its left side, the tumor exposed, and an incision about 6 cm. long made parallel with the spinal column, and about 1½ cm. to the left of the median line. After the fluid contents of the tumor had been evacuated, a second smaller cyst was found at the base of the larger. The walls of the larger sac contained no large nerve-filaments. The sac was dissected out and ligated as close to the spinal cord as possible. After the removal of redundant tissue the outer wound was also closed by suture, a considerable amount of tissue being included in the coverings, to act as a plug for the spinal opening. For two or three days after the operation the little patient continued in a stupor, with the fontanels sunken and the pupils contracted. After the fourth or fifth day the stupor gradually passed away and the child progressed to complete recovery. A ligature-abscess formed, but healed without trouble after discharging. The child was in good health a year after the operation.

Atrophy of Shoulder-muscles in the Sequence of Pleurisy.—Thévenet (*Lyon Médical*, 1894, No. 5, p. 157) has reported the case of a cook, fifty-eight years old, who, although having been exposed in the course of extended travel to numerous sources of infection, had seemed to have escaped all. He had, however, had four attacks of acute articular rheumatism, of which the third was complicated by a left-sided pleurisy, attended with a copious effusion. The fluid was spontaneously absorbed in the course of two months, but at the end of this time a little flattening of the left side of the chest was apparent, which became more pronounced in the course of the subsequent few months. When the man came under observation in his fourth attack of rheumatism, five years after the third, the left side of the chest was found greatly flattened and contracted, its circumference measuring an inch and three-quarters less than that of the right side at a corresponding point. In addition, all of the shoulder-muscles were notably atrophied, particularly the deltoid. Elevation of the arm was brought about almost solely by the trapezius. The arm itself was but little wasted, although its circumference a short distance below the acromion was but little less than that of the opposite member in a corresponding situation, in spite of the fact that the right was the more used. Moreover, the man complained that for two years there had been progressive loss of strength in the left upper extremity.

The weakness, however, could not be traced to any particular group of muscles. The dynamometer registered sixty upon the right and but twenty-five upon the left. In addition, cutaneous sensibility to touch, to puncture, to hot and to cold, was impaired upon the left half of the chest, the left shoulder and the left upper extremity. The anesthesia diminished progressively toward the periphery. It was believed that hysteria could be excluded and that the sensory and trophic changes were to be ascribed to the previous pleurisy.

Congenital Hydronephrosis Cured by Nephrectomy.—ADLER (*Deutsche medicinische Wochenschrift*, 1894, No. 7, p. 151) has reported the case of a child that at the age of two years began to show evidences of abdominal pain and distention, particularly upon the left side. After medicinal measures had been exhausted without avail, an exploratory puncture was made, and showed the swelling to be due to an accumulation of fluid containing small amounts of urea. An incision in the linea alba below the umbilicus disclosed the presence of a tumor occupying almost the entire abdominal cavity and compressing the intestines into a small compass beneath the liver. The wall of the sac was sutured to the abdominal wound, then opened and a portion excised. The tissue removed proved to be renal structure. Nearly a pint and a half of pale, clear fluid containing a moderate amount of urea and a small proportion of albumin was evacuated. After the operation the child was in good condition and the tumor slowly but gradually diminished in size, although the fistula persisted and urine was passed but seldom (about every second day) and in small quantities by the natural channels. Nephrectomy was not undertaken at this time, from a fear that the right kidney might not be in good condition. At a later date, however, the right kidney being detected in its proper position and not appearing of unusual size, and, further, the urine passed by the urethra being clear and without morbid constituents, while that from the fistula was turbid, albuminous, and contained renal epithelium, nephrectomy was determined upon and with some difficulty performed. The subsequent behavior of the case was entirely satisfactory, and at the end of four weeks the wound had closed and presented but a small granulating surface. The urine was now passed by the natural channels in larger amount than before and was of normal quality. The general condition of the child was also improved.

Hemeralopia.—At a meeting of the Medical Society of Nürnberg held some months ago, VEITH (*Münchener medicinische Wochenschrift*, 1894, No. 5, p. 97) made an interesting contribution to the subject of the etiology of hemeralopia. He detailed the occurrence of an epidemic of this uncommon affection during the months of April and May in an institution for the treatment of diseases of the eye. Twenty cases were observed. In all the acuity and fields of vision remained normal, but double or treble the usual amount of light was necessary for normal vision. In two-thirds of the cases xerosis conjunctivæ was present on either side of the cornea in the zone of the palpebral fissure. In all of these the bacillus of xerosis was found. In two cases the xerosis had extended to the cornea. There had been no exposure to intense light. The patients were not all derived from the poorer classes; some were well nourished, and all ages were represented. Investigation disclosed the interesting fact that similar epidemics had been observed from time to time in Nürnberg, and always in the spring. Similar epidemic prevalence of hemeralopia had also been reported in other places, likewise in the spring of the year and in marshy regions. From these facts the conclusion is reached that hemeralopia is probably an infectious disease, which may occur in epidemics, like other infectious diseases. The affection appears to depend upon certain local and periodic conditions. Individuals debilitated by nutritive disturbance seem especially predisposed to the infection. It is probable that the disease is dependent upon an exciting agent whose nature is not yet known.

THERAPEUTIC NOTES.

The Treatment of Tuberculosis in the Country.—DATZENKO (*Vratch*, No. 44, p. 1209; *Rev. de la Tuberculose*, 1893, No. 4, p. 382) relates some interesting observations upon pulmonary tuberculosis, made in the course of a period of ten years in country practice. There were in all 87 cases, 24 from the better class, and 63 from the peasantry. Of the former, 5 were cured, 6 died, 4 were improved, 6 remained unchanged, and in 3 the condition was aggravated; of the latter, 1 was cured, 29 died, 8 were improved, 14 remained unchanged, and in 11 the condition was aggravated. This marked disparity between the two classes of cases was due not only to hygienic and dietetic differences, but also to the fact that the peasants regarded the disease as incurable. The treatment employed was purely hygienic and dietetic. As much time as possible was spent in the open air, and a nutritious diet, including large quantities of eggs and milk, was insisted upon. Cod-liver oil was given in addition. To several creosote was administered in small doses. In the winter applications of cold water were made to the general surface of the body, and in the summer cold baths were taken. Medicines were only employed symptomatically. As a rule, improvement became manifest within a week of the institution of systematic treatment. Fever soon disappeared, and with it night-sweats; the anemia diminished in intensity; the bacilli in the sputum became fewer in number, and the expectoration progressively less in amount; the physical signs indicated a sclerotic process in the affected structures, and at the end of a year the patient was greatly improved in appearance. Of the six cases in which a cure was brought about, one had presented induration of the lungs; three, softening; two, cavities. Etiologically three of these gave the impression of having been contaminated by others; while in the remainder the transmission appeared to have been hereditary. All of the patients were young, between fourteen and twenty-four years of age.

PHILADELPHIA.

SATURDAY, MARCH 24, 1894.

THE OCCURRENCE OF DEFINITE TYPES OF EPIDEMICS OF CHOLERA.

THE differences in the extent, duration, and malignity of the various epidemics of cholera have long been a matter of comment, and KOCH, in his earlier writings on the subject, directed attention to two distinct classes of outbreaks, one explosive in onset, and often almost as suddenly disappearing, the other setting in insidiously, spreading gradually, perhaps never attacking a large number of individuals at one time, and generally dying out with the same slowness with which it commenced.

The development of the whole doctrine of the infectious diseases is the outcome of a putting together of the results of investigators who have attempted to acquaint themselves intimately with an individual infectious disease, and now for the first time we are able, thanks to the extreme care with which epidemics have been studied since the advent of the bacteriologic era, to clearly differentiate the two types of epidemic cholera, and to apply the knowledge thus gained in interpreting the varying characters of epidemics of other diseases.

The symptomatology of *epidemics*, as observed by the modern hygienist, is as definite and decisive as that of most *diseases*, and yet perhaps no more definite or decisive. In an epidemic, as in a disease, it is sometimes possible to make a diagnosis from a single symptom—but this is not the common experience—and in the majority of cases it is only by a careful consideration of all the phenomena involved that a certain diagnosis can be reached.

We shall attempt, therefore, to describe briefly, first, the main characteristics of each of the two types of epidemics, as they are seen in Asiatic cholera, and afterward to point out how there may be more or less marked deviations from the orthodox behavior, and even how there can be a definite blending of the two types in a given epidemic.

In an epidemic of cholera of the first type, individuals are attacked simultaneously in all parts of the affected region, and in this sudden outbreak no direct connection between the cases is traceable. In the second type, there is no even distribution of the choleraic patients; on the contrary, the disease appears in distinct groups or foci of individuals, and even in these groups the members are not taken ill at the same time, but one after another falls sick in chain-like progression. If we were to represent graphically the course of the epidemics, the curve corresponding to the first class of outbreaks would show a sharply ascending limb, rising suddenly to a high point, and then again almost as abruptly falling to near the base-line; the curve representing the second type would rarely go more than a short distance above the base-line.

It is evident that an epidemic of the first type can be accounted for only by the sudden and more or less even distribution of the infectious agent over the whole of the affected region, while in epidemics which conform to the second type the virus is not generally distributed, but is slowly communicated from one individual to another.

Now on analysis it will be seen that there are only a few conceivable ways in which a microscopic virus can be suddenly and evenly distributed over a large area of the population; practically, the only *viæ* to be thought of are the air, the water, the ground, and the food. Insects may be left out of consideration here, for many of the most violent outbreaks of cholera have occurred during the cold winter months. As to the air, while it is true that recent experimental evidence has shown that cholera-bacilli may under certain favorable conditions be carried to a few people by its agency, yet the actual transmission of the disease in this way has never been

demonstrated; and even if we leave out of account the speedy death of the cholera-bacilli on drying, it does not seem possible that distribution could take place through the air with that rapidity and evenness which would have to be presupposed did we grant such an origin for an explosive epidemic. From the many observations which have been made, the ground, too, notwithstanding the protests of the Munich school of hygienists, may be practically excluded as a carrier of the infectious agent in an epidemic of cholera of this first type. It is possible that small epidemics may be determined through contamination of food-stuffs with cholera-bacilli, but in none of the large outbreaks has the food-supply ever borne any constant relation to the distribution of the cases. By a process of exclusion, therefore, we are compelled in the first type to fall back upon the water as the medium through which the virus must be distributed, and the conclusions arrived at by negative argumentation have lately been manifoldly verified by the positive demonstration in such epidemics of the cholera-bacilli in the drinking-water.

Those who have opposed this view have brought forward the objection that frequently in cities which have suffered from an explosive epidemic, certain houses, or even whole streets, obtaining water from the general supply have been free from cases of the disease, and that, therefore, the distribution of the infectious material was too uneven to be accounted for by a contamination of the water-supply. If, say they, the water is charged with the choleraic virus, and everybody drinks the water, then everybody should have cholera. But in order that this objection may have any weight, it is necessary that the three following conditions obtain: 1. The virus must be soluble in water, and so permit an absolutely even distribution throughout the water-supply; 2. All individuals should drink the same amount of water under precisely the same circumstances; and 3. The susceptibility for infection must be the same in all individuals.

We have, however, abundant evidence of variations in individual predisposition to cholera, aside from the influences of filth, faulty nutrition, overcrowding, and occupation. It is easy to see, too, how the relations of different individuals to the contaminated water can bear on the possibilities of infection. Thus, while one man drinks scarcely any water, another may consume large amounts daily, and among those who drink the water it is necessary to consider not alone the amount taken, but the time of taking, whether on an empty or on a full stomach, what the conditions of the gastric and intestinal functions are at the moment, and whether or not excess of any kind has recently been indulged in.

But it is the conception generally held of the way the virus is distributed in the water which is farthest from the truth. The infectious material does not exist in the water in solution. In "water-epidemics," be they of cholera or of typhoid fever, we have to deal with comparatively crude *suspensions* of the bacilli, and it is to this fact that we are to look mainly for the explanation of the little irregularities which sometimes occur in a generally even distribution. Moreover, it is exceptional that the bacilli are present in infected water in large numbers—they are never present, for example, in anything like the amounts which we see in a bouillon-culture in the laboratory, but are relatively sparsely distributed. When we consider this fact, and also the irregularities which might follow the attachment of bacilli to firm objects, or to the walls of the conducting pipes, and those consequent on variations in the rapidity of the current in different parts of the system, the only wonder is that an outbreak can assume the generally even character so often seen.

All the points which we have here mentioned have been brought forward by Koch in his description of the cholera in Germany during the winter of 1892–93. He quotes, too, the answer of Farr to those who objected to the latter's view (based on the finding of eels in different parts of the water-system) that the virus in the epidemic of cholera in England in 1866 was spread through the drinking-water, owing to faulty filtration. It reads as follows:

> "Eels, as we have seen, were found in the water in a certain number of houses in East London. To argue that in hundreds of other houses no eels were found, and that therefore the company never distributed eels in the district, would be absurd. The fallacy of such reasoning is transparent. It assumes the form: If no eels are found in the waters of a certain number of houses, none exist in the waters of any houses. As the eels are limited in number they cannot be distributed universally, and the fact that they were discovered in one house and not in another would depend on laws and circumstances so intricate as to make the ascertained distribution anomalous, but not necessarily more anomalous than the distribution of the lower forms of organized matter, to which the phenomena of cholera in man are due."

We turn now to the second type of epidemic, in which the cases occur in groups (cholera-nests), the

members of which are stricken successively rather than simultaneously, and are all perhaps the offspring through several generations of a single primary case. While it is possible in some instances to trace a direct connection between the cases, it is not strange, considering the complicated nature of human intercourse, and the multiplicity of ways other than direct by which the bacilli could pass from the feces of one individual into the alimentary canal of another, that as a rule there is failure to discover all the links in a given chain.

If all cases of cholera were severe enough to come under the observation of physicians, if the danger of infection by the feces of a patient began or ended with his symptoms, and if contagion occurred only through direct contact with infected individuals, then, in spite of the intricate relations of commerce and society, we might possibly, with the aid of thorough bacteriologic examinations, succeed in making out and keeping track of each of the mem bers of a chain.

We know now, however, that cases of cholera occur in which the symptoms are so mild that they pass unnoticed, that there are even instances, unfortunately, in which considerable numbers of cholera-bacilli are present in the feces of an individual who has been exposed to infection, without the slightest disturbance being manifest, the person presenting absolutely no symptoms and making no complaint. We know further that in the ordinary course of the disease, the cholera-bacilli are present in the feces both before the onset and after the subsidence of the acute attack; and when, besides the direct contamination with the feces of cholera-patients, we remember the indirect methods of transmission through the linen, the clothing, the bedding, the food, or by insects, we can understand in a dense, and especially in a fluctuating populace, the impossibility of keeping track of the exact method of distribution of the microörganisms.

From what we have said, it will be apparent that the two types of epidemics of cholera may often—indeed, must often—be combined. In an epidemic, say, of the first type, which in the beginning is pure (*i. e.*, in which each of the early cases has arisen through infection by water), there must soon appear little secondary epidemics scattered throughout the place, which are true examples of the "chain-like" type; and again, it is easy to conceive how a single or multiple "nodular" epidemic, beginning definitely as type two, could be followed by a local or general explosive outbreak, depending on a local or general contamination of the water-supply.

A little reflection will teach that the cholera-curve, under certain circumstances, may not be decisive for the type of an epidemic under consideration, for if the water be only slightly contaminated, the bacilli being extremely sparsely distributed, the line of the curve may be low; or on the other hand, a multiple nodular epidemic may break out under such peculiar conditions as to make its curve approximate closely to that ordinarily seen in type one. The insufficiency of single symptoms for the diagnosis of the type is thus made strikingly evident. It will be seen that each epidemic should be studied for itself by a skilled hygienist, who will be able to decipher the puzzling symptom-complex, and to decide as to the nature of the primary epidemic, the origin of secondary or tertiary epidemics, and how much of the outbreak belongs to the one and how much to the other type.

TOXIC HYSTERIA.

In The News of October 28, 1893, we discussed the subject of traumatic hysteria, and sought to show that the recognized stigmata of hysteria, as established by the labors of the French school especially, are being utilized to some extent to characterize an artificial neurosis, which is called rather crudely "railway spine." We now come to another aspect of hysteria, which, if not of such daily importance as that aspect of the disease brought about by trauma, is still a major question in pathology, and of grave significance in diagnosis. We refer to the toxic origin of hysteria.

When Briquet wrote his classic treatise on hysteria, in 1857, he quoted as examples of the disease in the male the cases of seven men, of whom, by more than a coincidence, four were workers in lead. He himself seems to have been impressed with this significant fact. Two at least of these patients had presented some of the ordinary symptoms of lead-poisoning, so that in them the hysteric stigmata were in the nature of epi-phenomena, or post-phenomena, clearly distinguishable, but yet likely to be confused with the symptoms of saturnism by a careless observer. These cases presented a type which may still be seen occasionally; and this type presented two classes of nerve-symptoms—first, those that were directly due to the physical effects of the poison upon nerve-tissue, and, second, those

that were purely hysteric. This embodies the vital distinction upon which we would insist here. The proposition is that among the causes of hysteria must be included various toxic substances, among which the most prominent are alcohol, lead, mercury, carbon disulphid, tobacco, and morphin.

Alcohol has long been recognized as an hysterogenous poison. In this country, in fact, it is probably the only one of the group named that would be recognized generally as possessing this quality. The toper is such a common sight in hospitals that all his defects are recognized. Among males it is now thoroughly established that two causes especially, alcohol and trauma, are active in the production of hysteria. In 1874 Magnan described the hemi-anesthesic form of chronic alcoholism, a type which can leave no doubt of its hysteric nature. Later, Gautier, in describing the symptoms of chronic absinthism, indicated the hysteric character of some of them.

But one of the most notable contributions to the subject of toxic hysteria was the paper by Letulle, on the hysteria of mercurial poisoning. He showed conclusively that mercurial poisoning may be the cause of hysteric stigmata, such as tremor, anesthesia, paralysis, etc., and that this tremor, which of course is not identical with the organic tremor caused by mercury, is shown to be hysteric by the fact that it has been cured by esthesiogenic agents. Somewhat analogous results have been obtained in cases of lead-workers, already referred to. Landolt and Oulmont, in 1878, made the statement that saturnine hemi-anesthesia (one of the most common of the hysteric manifestations of lead-poisoning) can be transferred, and even cured, by magnets. Guinon, in his recent monograph on the exciting causes of hysteria, places lead-poisoning in the front rank.

The victim of the morphin-habit may display some of the stigmata of the grand neurosis. These are most likely to be observed during enforced abstinence from the drug, and hence may complicate the period of treatment and convalescence. It is needless to point out that a knowledge of this fact may give the physician great advantage and confidence under circumstances in which otherwise uncertainty and confusion might exist.

It does not appear strange, when the fact is attentively considered, that the various poisons should have an hysterogenous effect. We observe that this power has two methods of action: First, by the general toxic effect upon the nervous tissue; hence by lowered tone and resistance which permit any inherited or acquired neurotic tendency, as hysteria, to assert itself. Second, by a more direct psychic impression, such as shock, fright, or anxiety, which is the natural consequence in many persons of the knowledge that they are poisoned. This latter method of action is observed in those cases especially in which the poison has been taken accidentally, or not by voluntary act, as in the cases of lead, mercury, and, in fact, most other poisons. Hence this action is strictly analogous to that of other moral and physical causes of hysteria, such as trauma, acute disease, and violent emotion. This is a most important phase of the subject. Cases have occurred of long-continued hysteric perversions of the stomach, as anorexia and vomiting, after the ingestion by accident of a supposed violent poison, which in itself was really harmless, as in one reported case, in which saltpeter had been taken for Epsom salts. A somewhat similar case has recently come to our notice, in which a lady consulted a physician for a slight sore-mouth, caused by an ill-fitting set of artificial teeth. She was told that she was poisoned dangerously by mercury absorbed from the vulcanite plate. She immediately developed a train of hysteric symptoms, including tremor, of which the specialist proceeded to cure her. It is sufficient to say that she never had had true mercurial poisoning, but only the shock of being told that she had.

The anxiety and mental depression of some persons with chronic lead and mercurial poisoning are almost pathognomonic of the condition. These are purely psychic phenomena, and are closely analogous to some of the mental stigmata of hysteria. Hence they form a natural and fertile soil upon which may flourish a whole train of truly hysteric phenomena.

The symptoms of toxic hysteria are readily grouped among the now well-recognized stigmata of the great neurosis. But some of them have special prominence. The most common are tremor, anesthesia, paralysis of various kinds, and anorexia and vomiting. The list cannot be strictly limited, because it is possible that any form of hysteria can develop when an active and exciting cause exists; but those symptoms only are indicated that are most common. Paroxysmal hysteria is not so common as the inter-paroxysmal or permanent stigmata.

Closely allied in its hysterogenous power to these various toxic substances is ether. Surgical anesthesia may produce one or more of the hysteric symptoms. Such cases are frequently overlooked, but they may confuse the prognosis of cases, and they have ere now even figured in medico-legal proceedings. Persistent and violent tremor, purely hysteric, has followed ether-anesthesia, and even threatened to frustrate the object of the operation. The remedy has been found in a proper diagnosis. When chloroform and ether were introduced into practice queer complications sometimes arose from their powerful psychic influences and hysterogenous effects. Physicians were held responsible for the production of grave nervous complications—generally hysteric and usually misunderstood—and for even puerperal mania. Happily times are better, but these things are not altogether impossible even to-day.

The importance of the study of toxic hysteria cannot be gainsaid. As the symptoms closely simulate those of the organic action of the various poisons, they are most naturally confused with these latter, and the case must bear a double burden of disease. Nothing can be more discouraging, because the hysteric perversions will stereotype and perpetuate the appearance of the organic affection. Witness the tremor of mercurial poisoning, the hemi-anesthesia of lead-poisoning, and the vomiting of a supposed poisoning by saltpeter. Without a proper diagnosis and elimination of these stigmata it is not too much to say that there can be no progress made in the successful treatment of these cases. From a medico-legal standpoint the all-importance of diagnosis is obvious.

DANGER TO THE ARMY MEDICAL DEPARTMENT.

The Army Appropriation Bill, as reported by the Committee on Military Affairs to the House of Representatives, provides that no more appointments of assistant surgeons in the army are to be made until the number (now 125) is reduced to 90. As the army is not reduced, and as all the medical officers of the army are kept busy, this appears to be a very unwise attempt at economy. It would of course put an end to the Army Medical School for at least five or six years. The bill also maintains the reduction of the appropriation for the Library of the Surgeon-General's Office to $7000 instead of $10,000, as it used to be, and as it certainly ought to be, to meet the demands of the medical profession of this country; and it reduces the amount allowed for the purchase of medical supplies from the usual sum of $185,000 to $150,000. This means that new instruments and new drugs cannot be obtained by medical officers, and that the officers and enlisted men of the army cannot have the benefit of the improvements in methods of treating disease and injuries which are now so frequently discovered or devised.

The members of the medical profession of the country should inform their representatives in Congress that this is unwise economy, and that they should seek to increase the efficiency of the army medical department rather than to diminish it.

EDITORIAL COMMENTS.

One of the Difficulties of the Country Physician is described by a valued correspondent as follows:

I had been attending the ten-year old son of an illiterate white couple living seven miles in the country. Passing the mother in the road the other day, I inquired as to the boy's stiff leg. "Well, Doctor, 'taint much better. I ben usin' one remedy tho', that ef I could have kept it up I b'lieve 'twould er cured him." "What was that?" "I got some of these little red airth-worms, put 'em in a bottle, and hung it in the chimney corner tell they stewed down into a intment, and then rubbed him with it. The fust time hit seemed to help him powerful, but every time we opened the bottle hit made him sick and me too, so we had to quit."

What can rational medicine hope to do when it must deal with such superstition and ignorance? Her boy had a perityphlitic abscess when I called to see him, two months previously. This was treated by incision and drainage and he made a good recovery, except that he still held the leg in a flexed position. I had demonstrated to them how this must be overcome by massage and passive movement, but such silent agencies seemed less potent to their credulous minds than the powerful "airth-worm intment."

There are few things that more persistently and subtly sap the vital and scientific energy of the country physician than this combination of ineradicable ignorance and superstition on the part of those among whom he practises. The physician constantly sees those atrocious examples of medical cruelty and filthiness into which the primitive mind seems to slip as naturally as a crocodile into water. Identically the same fact, however, is seen in the "best society" of urban life, as illustrated by the popular fads and foibles of those who in other matters have good sense. Necklaces of amber beads and Hahnemann's bust are displayed in our drug-stores; faith-cure establishments can pay expensive rents on the most fashionable streets, and a popular newspaper distributes from its own office thousands of bottles of "patent" medicine. Verily, it requires a deal of humanitarian good-will and genuine missionary spirit to practise honest and scientific medicine among such folk, who are apparently worthy only of a sane man's contempt. The belief in medical magic will doubtless outlive every other form of superstition that has come down to us from savagery.

Some Dangerous Nuisances of City Streets.—It is almost a daily occurrence that the street-sweeping of certain cities is carried on without proper sprinkling. The result is that a blinding, mouth-filling cloud of filthy dust is raised that floats into every household for squares, and that is sucked into every lung that breathes it. To physicians, who know the danger of this, and even to the decently cleanly citizen of any calling, this is a shame that should not be permitted.

In cities with old-fashioned narrow streets and sidewalks, the ridiculously-small space permitted those who walk is further narrowed, often to four, or three, and even to two feet, by some strange blocks of stone near the edge of the sidewalk, over which people stumble, and by which they are not infrequently hurt. The old laws against profanity should be at least rescinded, or else these stones should be "discharged." They are never used, as all carriages now have steps to aid a few persons in alighting. If they, or the equally useless hitching-posts, were of any use to one or two people, the thousands to whom they are a nuisance might endure their broken shins and ruined dispositions with more equanimity, as they do endure the impertinent extension of door-steps half or three-quarters the way across the sidewalk. But the hitching-posts and stepping-stones, and often the doorsteps are as useless as the buttons on the back of a coat. Would they were as harmless!

The police of at least one of our cities have no sort of an idea that the poor people who happen to live in the houses have any rights, so far as quietness or sleep are concerned. The tyrants who drive the carts and wagons, who condescend to gather the street-dirt, the hawkers, the "musicians"—all the street-owners—bawl and howl at their poor animals or their fellows at all hours and times, and especially at night, with vocal energies to give a fog-horn lessons. The hoodlums, and especially the young ones, from ten to twenty years of age, occupy their every loafing hour of day or night with rivalry as to who can make the loudest, most hideous, and most inhuman yells and yowls. How many are made ill, how many prevented from recovery by these and similarly outrageous city noises?

Old-time and Modern Dentistry.—The sudden rise of the science of dentistry is a remarkable fact, as it is quite clear that the ancients were not far behind us in this art. There followed several thousand years in which the entire science and art consisted in pulling teeth, quite regardless whether the teeth were good or bad. In the memory of living men the public tooth-puller was a frequent offence of village street-corners and is probably still plying his lucrative trade in some parts of the United States. It is but lately that the dentists best known to Parisians were called "arracheurs des dents," or tooth-drawers, who had chairs on the Champs Elysées, where they extracted teeth in the presence of large crowds. It was the popular belief that, in order to support their proclamation that the operation was painless, as soon as the dentist got his pincers firmly fixed on the tooth, he whispered in the patient's ear, "Canaille, if you make the faintest squeak, I'll break your jaw." The arrival of the American dentists, forty years ago, gradually banished these worthies from the public view, and gave dentistry the rank of a profession, and made its processes more humane and scientific. But dentistry is still in France a great refuge for quacks and impostors, as there is no proper legal control of the art and no diploma is required for the practice of it.

Privileged Testimony of Physicians which Cannot be Stricken Out.—Conceding that a physician is an incompetent witness in a given case, upon the ground that his information has been acquired while attending a person as his patient, and which it is against the policy of the law for him to divulge, the Supreme Court of California holds, in the recently decided case of Wheelock *vs.* Godfrey, that if the patient, as one of the parties to a suit, introduces testimony of the physician which, in the face of an objection, would be incompetent, he cannot strike it out upon discovering that it militates against him, without the consent of the opposite party. By offering the witness, and eliciting testimony from him, he in effect declares the witness as competent and the testimony proper. In the absence of objections on the other side, it is the equivalent of consent, and is as binding upon the parties as a written stipulation agreeing to the competency of the witness to testify to the given facts would have been.

Unsoundness of Mind and Incapacity for Business are Correlative.—Unsoundness of mind and an incapacity for the transaction of business are correlative; each implies the other—says the Supreme Court of Indiana in the recently decided case of Teegarden *vs.* Lewis. When a person is so far deprived of reason that he is no longer capable of understanding and acting with discretion in the ordinary affairs of life, he is insane, within the meaning of the law; in other words, want of capacity to act with discretion in the ordinary affairs of life is evidence of unsoundness of mind. And when a person has been found to be of unsound mind, the law infers that he is incapable of transacting business. Not only cannot a person of unsound mind enter into a valid contract, or make a valid will, but he cannot even make a valid gift.

SELECTIONS.

THE PROHIBITION ON CHEMIC INDUSTRY IN AMERICA.

Over a quarter of a century has rolled by since the smoke of battle cleared away and the din of arms ceased to resound throughout America. The arts of peace have been cultivated for a generation, and one by one the oppressive measures, made necessary by a state of war, have been repealed or have lapsed by limitation. Only recently the press heralded the repeal of the Federal Election Laws as "the wiping out from our statute books of the last of the war measures," and all true Americans, victors and vanquished, Republicans and Democrats, all—save a few blood-thirsty non-combatants—rejoiced together over the fact.

But is it a fact? Every pharmacist in the land, from the great manufacturer down to the modest country apothecary who makes a few tinctures and fluid extracts, knows that it is not. He knows that the art and science of pharmacy, the art and science of medicine, and their clients, the sick and suffering of the country,

still groan and labor under a war measure which, however necessary it may once have been in its inception, has for years past been more onerous, unjust, and shameful than any for whose repeal at least one great party has been clamoring—the tax on alcohol for manufacturing and medicinal purposes. It still stands on the statute books, a war burden, after thirty years of peace; a tax on the sick and suffering, a paralyzer of industries, as foolish and short-sighted as it is unjust and iniquitous.

And now, when the proposed revision of the tariff had given the pharmaceutical profession reason to hope for its repeal, or at least mitigation, comes the notice that it is proposed to increase the tax and duties on alcohol.

This is a blunder—a worse than blunder. It is an outrage on a long-suffering class, as well as a blunder from an economical point of view, and one so plain that it would seem that any person of common-sense would see its folly. Let Legislatures and Congress put all the tax they please upon liquor intended to be used as a beverage; let them throw all the difficulties they please around the distillation of and trade in it, and few decent men would care to raise their voices in protest; but when it becomes a question of retaining prohibitory tariffs or taxes on alcohol for use in medicine and in the arts and industries, every sane individual should unite in protest.

The tax on alcohol for these purposes, and the inanities of our laws regulating the registration of trademarks, by which foreign patentees have every advantage over Americans, have paralyzed chemistry and chemical industries in this country, and have forced us to import from Germany and France millions, yes, hundreds of millions, of dollars worth of chemicals, drugs, and medicines that would otherwise have been manufactured in the United States; they have carried hundreds, possibly thousands, of millions of dollars abroad during the past thirty years that should and would have stayed in this country, but for these fool statutes. Further than this, with our vast surplus of cereals, enabling us, were it not for the tariff and taxes, to produce alcohol cheaper than any other country on earth, the United States might have been the exporter of untold millions in chemicals to the balance of the world.

Just as long as we allow Schering, and Merck, and the host of other *Chemische-fabriken auf Actien*, *Farbenwerke*, etc., to patent their goods and register their trade names in this country, without reciprocity, and to appoint their "sole agents" and representatives in this country, through whom all orders for goods must pass (thus creating a monopoly on a monopoly); just as long as we do this, and forbid Americans to manufacture chemicals, by placing the most important article in their manufacture at so enormous price that its use and employment is ruinous—just so long will we be importers, instead of manufacturers and exporters, to the extent of hundreds and thousands of millions of dollars.—*National Druggist*, March, 1894.

THE PREPOSTEROUS CLAIMS OF HOMEOPATHY.

It is time that the preposterous claims to originality made by homeopaths in regard to what they are pleased to call their materia medica were exposed and refuted. As a matter of fact there are few, if any, drugs in the so-called homeopathic list of remedies which are not taken bodily from French or German works on drugs, many of which are either out of print or forgotten. It would be as easy to show that the pretended discoveries of the homeopaths are in fact plagiarism as it is to demonstrate that *similia similibus curantur* is a fallacy in the logical sense of that word.

Every practical student of therapeutics is aware of the fact that all substances, whether fluid or solid, which have any action on the organism produce two apparently opposite and contradictory series of effects, resulting from their exhibition in different doses, or, in some instances, observable in successive stages of their operation. Thus, to take a familiar example, opium acts as an excitant in one dose and as a sedative in another dose, the precise proportions required to produce the several effects varying with the individual, but the two phenomena being presentable in every case. Castor oil may stand for a drug which promotes peristaltic action in one part of its operation and checks it in another, not by producing exhaustion as is too commonly assumed, but specifically, as was found by the experiments made with castor oil during the prevalence of cholera. Better illustrations of the fact to which I allude might be found, but these occur to me as familiar. Now it must be evident that if this be so *every* drug may be claimed as a "similar" by any one desirous of propounding the dogma *similia similibus curantur*, and ignorant or careless of the fact that all drugs have contradictory actions in different doses. The fallacy of the homeopathic system lies in this, namely, that the drugs employed by homeopaths are never given to cure disease in the doses which they allege will produce effects similar to the morbid phenomena they affect to regard as "indications."

In brief, the whole pretence is a juggle. Setting wholly aside the absurdity of infinitesmal doses, the very principle is a fallacy.—Mortimer Granville, *Medical Press and Circular*, No. 2856, p. 107.

CORRESPONDENCE.

MEDICAL PROGRESS IN CLEVELAND, OHIO.

To the Editor of The Medical News,

Sir: At the last meeting of the Cleveland Medical Society, March 9th, nearly three hundred physicians were present. The Society had lately so amended and revised the Constitution and By-laws that physicians may be admitted from all parts of northern Ohio; and in response to the invitations sent out, thirty applications were received for *non-resident* membership. The Society now numbers over two hundred *resident* members, and is steadily growing.

At this meeting Dr. Howard A. Kelly, of Johns Hopkins University, Baltimore, read a paper entitled "A Consideration of Intra-abdominal Pressure, with Practical Deductions applicable to Gynecology." He was listened to with close attention, and the many practical points deduced were received with marked appreciation.

This was the first of a series of papers to be read

before the Society during the year by prominent men from other cities.

Professor Kelly presented to the Society a rare old book—a copy of the work on anatomy published by Vesalius in 1514, and also one published by Tulf, in Amsterdam, in 1716, entitled *The Century of Observations*. These were given for a nucleus around which the Society hopes to gather a large medical library. Several large and valuable private collections have been offered, and the Society waits only for a permanent headquarters in a fire-proof building.

One of our distinguished guests said: "I am glad that I came, as I have never before in my life seen such a gathering in a local medical society. A sort of medical revival must have struck Cleveland. I venture to predict that the enthusiasm shown is indicative of a great future for the Society. The accumulation of a medical library requires time more than anything else. Books are donated rather than purchased, but I am sure that a large medical library will be rapidly collected in this great and growing medical center, through the efforts of your Society."

Dr. M. J. Parker read a paper on "Hypnotism," and ex-Judge Wing opened the discussion by setting forth the medico-legal aspects; Dr. Henry S. Upson following with views from the "medical standpoint."

On the following morning, Dr. Kelly gave a clinic in Charity Hospital before an immense number of physicians, many of whom were from neighboring cities and towns. He first catheterized the ureters in a case of suspected hydro-nephrosis—illustrating in the clinic many things of which he had spoken the previous evening.

The second case was one of retroversion, which he brought into slight anteversion by two sutures through the posterior uterine and anterior abdominal walls. His method of suturing the abdominal wound was much appreciated. He used three sets of sutures, and *all* buried. The last set brings together the cut surfaces of skin—the stitches *not* piercing the epithelial layer, and arranged in semblance to "the walls of Troy." The last operation was one upon a pelvic abscess, which was opened and drained through the vagina.

FOOT-BALL AT WEST POINT.

To the Editor of The Medical News,

Sir: In your issue for March 3, 1894, p. 250, I published some comparative statistics as to accidents from foot-ball, riding, and in the gymnasium at West Point, covering three months, from September 1 to November 30, 1893. On writing to Dr. P. F. Harvey, post surgeon, to learn whether similar statistics had been kept for former years, I find that the only statistics available are in the following table for 1892. For the purpose of comparison I have put the percentages of 1893 and those of 1892 side by side.

Comparative Statement of Injuries to Cadets from Foot-ball, Riding, and Gymnastics at West Point, N. Y., for a period of Three Months in 1892.

1. *Injuries of all Kinds.*

	Number.
Foot-ball injuries, Sept. 1, 1892, to Nov. 30, 1892	37
Injuries in Riding Hall, Oct. 15, 1892, to Jan. 15, 1893	26
Injuries in gymnasium	10

2. *Number of Men.*

Who played foot-ball	27
Under instructions in riding hall	198
" " in gymnasium	101

3. *Days Lost.*

From foot-ball accidents	106
Riding injuries	71
Accidents in gymnasium	38[1]

	1892.	1893.
Per cent. of accidents per man in foot-ball	1.05	1.6
" " " " " riding	0.11	0.09
" " " " " gymnasium	0.10	0.08
" " days lost per man in playing foot-ball	3.93	8.01
" " " " " riding	0.35	0.31
" " " " " gymnasium	0.57	0.15
" " men off duty per diem in foot-ball	1.18	3.01
" " " " " " riding	0.79	0.63
" " " " " " gymnasium	0.64	0.12
" " days lost per accident in foot-ball	2.98	5.01
" " " " " " riding	2.74	3.04
" " " " " " gymnasium	5.80	1.02

It will be observed that there is but little difference in the two series of injuries. The serious disproportion, therefore, against foot-ball, as compared with the two other forms of athletics, seems to be normal rather than accidental.

One other point to which Dr. Harvey calls attention, and of which I was not aware when I wrote the last letter, emphasizes very clearly the relative frequency of the accidents. Foot-ball games, he states, are played only on Saturday afternoons. Instruction in the riding hall is given three times a week, and in the gymnasium six times a week. "In other words," as Dr. Harvey says, "if accidents always happened in the ratio here given, the number which *would* have occurred in foot-ball had it been played as many days as instruction in riding was given would have been *three times* the number stated, and *six times* the number if played as often as instruction in the gymnasium was given.

Very truly yours, W. W. Keen.

1729 Chestnut St., Philadelphia.

THE TREATMENT OF CHRONIC ALCOHOLISM BY HYPNOTIC SUGGESTION.

BY G. E. BUSHNELL, M.D.,
ASSISTANT SURGEON U. S. ARMY.

THE treatment of chronic alcoholism has of late become a matter of especial interest to the medical profession of this country in view of the popularity of various secret "cures" for that condition. No unprejudiced observer can deny that these methods of treatment have cured some drunkards of their addiction to liquor, for periods of some years at least. Although such so-called "specific" treatments have been repeatedly denounced by the medical press, it is a fact that many physicians send patients to the institutions in which such treatment is given, or have adopted or attempted to imitate their medicines. It appears to be generally admitted that strychnin and atropin are the active drugs in these secret compounds, and we may well inquire whether the success of such treatment is or is not due to these alkaloids. During the past three years I have experimented with hypnotic suggestion in the treatment of chronic alcoholism and have obtained results practically identical with those reached by these methods, but in the great majority of cases in less time and without giving a drop of medicine of any kind. It is, therefore, a fair inference that in the methods of "specific" cure the psychic effect produced by the frequently-repeated hypodermatic injections, by the symptoms arising from physiologic doses of powerful alkaloids, and by the expectant attention of the hopeful patient, is of more importance than the character of the drugs employed. It is true that the hypodermatic administration of the nitrate of strychnin was recommended by Russian physicians in the treatment of alcoholism before Keeley became known to fame, yet it is to be noted that Dr. Korona, of Tiflis, who has had a very large experience with this method, raises the question whether its effect may not be largely due to suggestion.[1] This question can only be answered by the experiment, which has never been tried so far as I know, of treating an alcoholic subject with hypodermatic injections of strychnin without allowing him to suspect that the object is the cure of his appetite for liquor. But even if strychnin alone or in combination be granted to exert a specific influence upon the liquor-habit, as the tendency of alcohol is to produce fatty degeneration, the use of so powerful a cardiac stimulant as strychnin is not without danger of causing the sudden death of the patient from over-excitation of a fatty heart. This fact is recognized in the Keeley institutes. A careful examination is made of the heart of all applicants, and those are refused treatment in whom there is any reason to suspect the existence of this degeneration, thus excluding a class which most urgently needs deliverance from the liquor-habit.

The hypnotic treatment of alcoholism appears to be little known in this country. I have been obliged to work without much assistance from the literature of the subject, which is for the most part not easily accessible, and the views which I shall present are almost wholly the result of my own experience. The following is a condensed report of all the cases of chronic alcoholism which I have treated by hypnotic suggestion.

CASE I was that of an American blacksmith, thirty-four years of age. On January 26, 1891, this patient, alarmed by the sudden death of one of his companions from alcoholism, came to me for treatment of the liquor-habit, saying that he knew that he would die within a month if no help was given him. He stated that he had eaten absolutely nothing for two weeks and very little for six weeks, and had consumed an enormous amount of whiskey. For several years his minimum allowance for twenty-four hours had been two bottles of cheap whiskey, one of which he drank during the day while at work, the other during the night. He could not sleep without a preliminary drink of whiskey, and waking in an hour or less was obliged to drink again to procure more sleep, and so spent every night alternately drinking and dozing. He had tried to stop drinking, but an abstinence for a period of nine hours had produced such alarming nervous symptoms that, fearing delirium tremens, he had felt himself forced to continue the habit. Having previously treated him medicinally with very little benefit, it occurred to me that this would be an excellent case upon which to test the merits of hypnotism. I accordingly told him that I had read of a new treatment of which I had no personal knowledge and which I would like to try upon him. An unsuccessful attempt was made to hypnotize him on the following day. A second attempt, on January 28th, was successful, and appropriate suggestions were given. The treatment was continued on Feb-

[1] Wetterstrand: Der Hypnotismus, p. 62. Vienna, 1891.

ruary 3d, 4th, 5th, 6th, 7th, 8th, and 15th. The patient was allowed to drink during the first part of this period. He reported after the first two treatments that the liquor had a "brown" taste and that he found the same quantity much more intoxicating than formerly, so that he was able to reduce the amount consumed without discomfort. After the fifth treatment he felt a sudden repugnance to liquor and returned to announce that he was completely cured. It was with difficulty that he was persuaded to return for further treatment. His health rapidly improved, his appetite for food returned and became for a time enormous, his digestion was good, and his sleep sound and refreshing. He abstained from liquor entirely until November, 1891, when he began to drink again on account of the intolerable itching and burning due to an acute attack of some skin-disease, but perceiving that he was rapidly relapsing into his former excess he consulted a local physician (my station having been changed in July, 1891), who gave him a brief course of treatment after one of the methods of "specific" cure. This removed the returning cravings, and on September 1, 1893, he reported that he was still entirely abstinent.

CASE II.—A Swedish laborer, a very hard drinker, was intoxicated when first treated, on February 17, 1891. The treatment was repeated on the following day, the patient being much under the influence of liquor. On February 19th he presented himself grossly intoxicated, at an hour other than that which had been appointed, and was told to return at the proper time. Taking offence at this he did not come back for further treatment. I met him a month later so improved in appearance as to be hardly recognizable, when he volunteered the statement that as the result of the treatment he could no longer drink whiskey, but that he was still drinking beer. He was seen two months afterward lying in the gutter dead drunk, having probably succeeded in overcoming his distaste for whiskey.

This incomplete case is of interest, because it shows that well-marked temporary results can be obtained from even two hypnotizations given under apparently unfavorable conditions, and that the effect of the treatment does not always manifest itself at once. The patient could drink whiskey on the day after the last treatment, but at a later time, unfortunately I do not know exactly when, it became for a considerable period repugnant to him.

CASE III was an English shepherd, aged thirty-seven, formerly a sailor. He drinks heavily when able to obtain liquor, and was somewhat intoxicated when first treated, on February 22, 1891. After three treatments the patient obtained employment at a distance, and was lost sight of. I supposed that the treatment had not been long enough continued to secure more than temporary results, but happening to meet him on September 1, 1893, he most positively assured me that he had not touched liquor since my treatment of him two years and a half before. The fact of his sobriety was attested by his friends.

CASE IV.—A Scotchman, aged forty-three, a sheep-owner, a man of intelligence and education, drank whenever in town, at first convivially, afterward by himself. He has acquired the habit of sipping liquor during the night in order to sleep. He was hypnotized on the third attempt, on March 13, 1891, and received in all nine treatments on consecutive days. He did not drink after beginning the treatment, and all desire for liquor speedily left him. At the conclusion of the treatment he was unable to taste whiskey without becoming nauseated. He abstained from liquor for about eight months; then having lost his disgust for it he began to drink again, moderately at first, but soon as hard as ever. He then took a course of treatment at a "Keeley" institute in Nebraska, and since then has abstained entirely. The following is an extract from a letter received from him, dated February 31, 1893: "In regard to the two treatments, hypnotic and 'Keeley,' I cannot see any difference between them. They act in the same way—that is, on the mind. Your treatment was every bit as effectual as the Keeley, but I made a great mistake with yours. I expected too much from it. I used to take whiskey when I really did not want it, thinking that my mind was so strong that I could call a halt whenever I pleased, and the result was that the old desire came back, and I believe worse than ever. Of the two treatments I would say that they are both equally good, and will cure anyone that wants to be cured, but neither of them can put a new set of brains into a man. It is for the subject to stay cured; when he is [cured], and not experiment as I did with the hypnotic."

CASE V.—An American, aged fifty, a bartender, drank to excess periodically. When he consulted me he had been drinking steadily for several weeks, and was tremulous and nervous, and he had been with difficulty persuaded by his employer to submit to the treatment. On March 26, 1891, he was hypnotized with great ease, but only to a slight degree, as he continued to talk volubly about his sensations. The treatment was continued March 28th, 29th, and April 5th. The effect of the treatment in controlling his appetite for liquor was not marked. He continued to drink beer, but did not become intoxicated. On April 6th, contrary to my advice, he went with others on a hunting-trip, from which he was brought back in three days very ill. It was stated that he had fallen from the wagon and injured himself. The only injury apparent was a large ecchymosis about the left eye. There were rumors of a fight having occurred, and there was little doubt that the hunting-trip had been little else than a debauch with liquor. The patient was delirious, and could hardly be kept in bed by constant watching. There was constant tremor, which affected the tongue and muscles of the face, so that speech was apparently impossible. The temperature was slightly elevated. He died on the third day after his return. A careful examination of the brain *postmortem* discovered no gross lesions, except dense and old adhesions of the dura over the vertex, enclosing a small cyst which contained colorless fluid. It is my opinion that the cause of death was delirium tremens, that the patient had indulged in whiskey with his accustomed freedom, and that the

effect of the hypnotic treatment had been to cause an intolerance of alcohol, which in his broken health led to a fatal result. (Compare in this connection Case XIV.)

CASE VI.—A German, aged thirty-two, a cavalry non-commissioned officer, has consumed beer in large amounts for years, and recently had been drinking whiskey also to such an extent as to unfit him for the discharge of his duties. Brought for treatment by his captain, December 5, 1891, he himself had no desire to give up drinking, and consented to the treatment with the reservation, as he subsequently admitted, that he would continue to drink if he could. He was readily hypnotized, and received further treatment on December 6th, 7th, 8th, 10th, 17th, 25th, January 10th, 17th, 25th, 31st, and February 17th, 1892. He professed to have lost all desire for beer and liquor after the fourth treatment. It was discovered, however, that he still drank beer when he thought he could do so undetected. He was given five treatments during the month of March, and two in the early part of April, after which he again claimed to be cured. On April 17th he left the post with his troop and made a march of 300 miles through a country where the drinking-water was scarce and bad. On this march he was almost constantly exposed to snow and rain, and had much wearing responsibility; but although opportunities for obtaining liquor were not lacking, he abstained entirely and remained sober after his return until May 18th, when he began to drink again, owing, he said, to the worry and excitement arising from a fire which consumed his company-barrack. After another slight relapse on Decoration Day he remained apparently sober, although he drank beer occasionally, until December 4th, when he became somewhat intoxicated and was admitted to the post hospital as a preventive measure. He then claimed to have a sincere desire to reform, and ascribed his relapses to his inability to resist the solicitations of his friends, yielding from a wish to be sociable, rather than because he had any actual craving for intoxicants. He received occasionally hypnotic treatments during the winter and the early spring, and is thought to have abstained entirely during this period from beer as well as whiskey. In the latter part of April, 1893, he left with his troop for duty at another post, upon his arrival at which he withstood so well his many old comrades who urged him to drink in honor of the meeting, that his captain thought him really cured. But soon afterward, without any known cause, he began to drink heavily again. His term of service expiring in the summer, he was discharged and his present condition is not known.

CASE VII.—An Irishman, aged forty-six years, was a soldier who had served nearly thirty years in the army. He was "a man who," to quote his captain's words, "was never sober except in the guardhouse, or when it was impossible to get rum enough to make him drunk. And for rum he would trade the shirt off his back." He was treated every day for six days, beginning on December 21, 1891, and then at gradually increasing intervals, receiving in all fourteen treatments. The desire for liquor left him after a few treatments, and he remained sober under many temptations for about six months. During this period he made the long march referred to under Case VI. On this march he carried whiskey for some of his comrades who were afraid to trust themselves with it, but felt no desire whatever for it. In May, 1892, his troop left the post for duty in another department, the transfer involving a march of nearly three hundred miles. On this march he became intoxicated once, and also drank a little after reaching the end of his journey. He then remained sober for several months, but finally relapsed completely into his old habits.

CASE VIII.—An Englishman, aged forty-seven years, was a soldier in the same troop as the preceding case. He had served twenty-nine years in the army, and was a most incorrigible drunkard—on the verge of discharge on account of his addiction to liquor. He received eleven treatments, beginning on January 28, 1892, and abstained entirely from liquor for about four months, but became intoxicated while on the march in May, 1892, and continued to drink at intervals for several months, finally becoming as bad as ever.

CASE IX was an American soldier, aged forty-eight years. The patient had suffered many years from insomnia, for which he had consulted many physicians, and had had much ineffectual treatment. He had used beer and whiskey to procure sleep until he had become much addicted to them. Treatment was begun on December 27, 1891, at which time the patient was recovering from the effects of prolonged intoxication, and had been treated for two days with hypodermatic injections of strychnin. He received twenty-eight treatments during the following three months, the relatively prolonged course of treatment being directed against the sleeplessness rather than the desire for stimulants, which was quickly removed. The duration of his sleep increased from an average of two or three hours to six or seven hours, and the sleep became quiet and refreshing. He abstained entirely from alcoholic beverages of every kind for about six months from the beginning of the hypnotic treatment. Whiskey he had a strong dislike for at that time, but beer was not disagreeable to him, and he began in the latter part of 1892 to drink an occasional glass for sociability's sake, but one glass did not excite a desire for more, and he did not become at all intoxicated until the spring of 1893, when, being obliged to spend six weeks away from home without any occupation, he drank beer in larger quantities, and the old appetite for whiskey returning temporarily, he indulged freely in it and was drunk for nearly a week. Returning to his home he received two hypnotic treatments for a recurrence of the insomnia, which is partly a cause and partly an effect of his habits with regard to alcoholic drink, and since that time he has slept comparatively well and has remained sober, although being unwilling to give up the social enjoyment which he finds in a glass of beer with his friends; he will probably relapse again in time.

CASE X was an American, aged thirty-six years,

a laborer, and a notorious drunkard. He had been drinking steadily for about twelve years. He estimates his daily consumption of whiskey to have been more than a quart, but adds that that limit is set only by his inability to pay for more. February 15, 1892, the patient presented himself considerably intoxicated, and was hypnotized with ease. He received treatment every day, and continued to drink moderately until February 21st, when the desire for liquor left him entirely, and he was so confident that he was permanently cured that he would only return for one more treatment, on the 24th. He secured employment in a saloon and gambling-room where whiskey was constantly before him, but did not drink at all until the end of August, 1892. At this time he began to gamble, to which his employer objected, and he lost his situation. Continuing to gamble he lost the savings which he had accumulated during the preceding months of sobriety, and began to drink again, his friends think on account of his losses. He soon appeared to be in as bad a condition as before the hypnotic treatment. His wife, however, states that he did not continue to drink until he was as deeply intoxicated as formerly; also that he was apparently more affected by the same amount of liquor. He left this vicinity soon after his relapse, and has but recently returned. At present he drinks at times to intoxication, but thinks that liquor has not the hold upon him that it had before he received the hypnotic treatment.

Case XI.—An American soldier, aged twenty-nine years, had been addicted to the use of liquor for twelve years. He had been in the habit of drinking greater quantities of whiskey, he says, than any man of his age whom he knows—sometimes as much as two bottles and a half a day. He has had two attacks of delirium tremens, in one of which he ran until completely exhausted, under the delusion that his company officers were trying to kill him. He has repeatedly tried to conquer the habit, and has abstained from liquor for periods of varying length, the longest of which was six months, about ten years ago. At such times of abstinence almost irresistible cravings for stimulants come upon him suddenly—sometimes without apparent cause, but always if he sees others drinking. He has taken no liquor since January 18, 1892. Beginning on February 24, 1892, the patient received six treatments on successive days; also treatments on March 8th, 15th, 24th, and April 24th. The treatment was successful in removing very quickly all desire for liquor. The craving returned for half an hour on March 20th, but he resisted it, and since that time has abstained without any effort. He is confident from past experience that it would have been impossible for him to have remained sober for so long a time unaided.

Case XII.—An American, aged forty-four years, a cattle-owner, used liquor and tobacco to excess. He has suffered with insomnia and has a "tobacco heart." He desires to be cured of the appetite for both liquor and tobacco. The patient received nine daily treatments, beginning on April 2, 1892. He continued to use liquor until on the 7th a drink of whiskey caused an attack of nausea and vomiting which lasted two hours. He could, however, still smoke until the evening of the 8th, when a cigar produced an attack of nausea of briefer duration. Since that time he has abstained from the use of both liquor and tobacco, and has felt no desire for either. His sleep has become quiet and refreshing, and of sufficient length, and his heart gives him no further trouble. He was last heard from on July 7, 1893, at which time he wrote that he was still abstinent, that whiskey had no temptations for him, and that even the smell of it was disgusting, and he regarded himself as permanently cured of the liquor and tobacco habits.

Case XIII.—An American soldier, aged twenty-five years, had been drinking for three years. He received eight hypnotic treatments, the first on April 8, 1892. He felt no desire for liquor, and did not drink at all until detailed for duty at the department rifle range in the summer of 1892, where, the water being bad, he drank beer occasionally, but did not become intoxicated. On his return he continued to drink beer at intervals, but claimed to have no craving for it. He, however, yielded gradually to the attractions of conviviality, and has of late been intoxicated several times. In this case it appears that the indulgence in alcoholic drinks is due rather to a fondness for excitement and conviviality than to any actual physical cravings.

Case XIV.—An American soldier, aged forty-seven, had been drinking for fifteen years. He drinks beer steadily and has occasional "sprees" with whiskey, which last about two weeks. On June 6, 1892, the patient was hypnotized while somewhat intoxicated. The treatment was continued on the three following days, after which he failed to present himself. On June 10th the patient had continued to drink, but found that whiskey affected him much more strongly than formerly. He was admitted to the hospital on the verge of delirium tremens, very nervous and seeing visions, but recognizing them to be hallucinations. He was kept in bed for ten days and the hypnotic treatment suspended. On June 20th the patient said that he recognized that he could no longer drink whiskey and was resolved to abstain in the future. He was hypnotized and the same treatment continued on the two following days. He was sent to another post in January, 1893, where he was seen in the latter part of August. He stated that he had drunk whiskey once, and found it so disagreeable that he had no desire to continue to drink, and that he believed himself to be permanently cured of his fondness for it.

Case XV.—A non-commissioned officer, an American, aged thirty-one, had been drinking for twelve years, chiefly beer, but occasionally as much as a quart of whiskey a day. Ten years ago he abstained from strong drink for five months. Since then he has repeatedly tried to reform, but has always quickly broken his good resolutions. After three weeks of hard drinking he was admitted to the hospital November 21, 1892, suffering with extreme nervousness and hallucinations of sight and hearing. He was kept in bed and treated medicinally until the 27th, when

hypnotic treatment was commenced. He received eight daily treatments and three others at lengthening intervals. The marked improvement in his appearance after this course of treatment and the new zeal with which he performed his duties were matters of general remark. The craving for liquor had apparently left him, and he remained sober until February 23, 1893, when, being in Omaha, he met friends who urged him to drink with them. He refused repeatedly, but finally began to consider that, the day being cold, a glass of liquor would warm him up, and, dallying thus with the temptation, a sudden desire came upon him. He drank until he became deeply intoxicated, and continued to drink heavily for two weeks. Returning to the post, he received ten additional treatments, but continued to drink beer in spite of many vows of abstinence. It appeared that, knowing that he had once tried to abstain and had failed, his comrades joked him about it, and he had not the moral courage to refuse. The beer affected him much more speedily than before the hypnotic treatment. Whiskey he was unable to drink. I finally gave him up as incorrigible. As for his present condition, he still drinks, but not to great excess. He is no longer a "good beer-drinker," although he once prided himself upon being one of the best. Whiskey is still unpleasant to him, and he rarely touches it.

CASE XVI.—An English non-commissioned officer, aged thirty-seven, was induced by his company commander to come for treatment on October 23, 1892. He drank to excess at irregular intervals. The patient was given the hypnotic treatment, with the usual result of loss of tolerance of alcohol, but he continued to drink to excess at intervals of a few months. Being questioned after a period of intoxication, he frankly said that he did not intend to give up drinking, that the only pleasure which he had was in associating with his friends, who were drinking men, and that he could not enjoy their society without drinking with them.

CASE XVII.—An American ranchman, aged fifty, had been for many years in the habit of taking liquor before going to bed in order to procure sleep. The appetite thus acquired has much increased during the past eight years. He has been drinking excessively for several months and is nervous and tremulous when he appears for treatment. He was hypnotized with difficulty on the fifth attempt on December 4, 1892, and received eleven treatments. The patient continued to drink whiskey during the first few days of treatment. In the afternoon of the day upon which the third treatment had been given (December 6th) the desire for liquor left him suddenly and completely. He took a small quantity of whiskey on the following morning, but found it, as he said, "like medicine." Since that time he has abstained entirely and without effort from all intoxicating beverages, and his sleep and general health have been satisfactory.

CASE XVIII.—An American soldier, aged twenty-two, had been drinking for four years. He received eleven hypnotic treatments, beginning January 21, 1893. The patient stated that the desire for liquor which he had formerly experienced was completely removed by this course of treatment. He remained sober while at this post. On April 17, 1893, he left with his troop for duty at another station, since which time his history is not known.

CASE XIX.—An American soldier, aged twenty-nine, had been drinking for twelve years and for the last three years very heavily, sometimes more than two quarts of whiskey a day. He has often tried to give up drinking, but has never been able to abstain for a longer period than one month. On March 25, 1893, the patient came for treatment, weak and nervous, after prolonged intoxication. He was given six treatments on successive days and five others at longer intervals, with the usual result of speedy loss of appetite for liquor. On September 20th the patient came for additional treatment. He had taken no alcoholic drinks since March 23d, but since last pay-day (September 7th), seeing his friends drinking, he has had a return of his former cravings for liquor, but has resisted, awaiting my return to the post. He was given three hypnotic treatments. The cravings for alcohol left him after the first treatment and have not since returned. He has been perfectly sober up to the present time.

CASE XX.—A German soldier, aged thirty-seven, began to drink five years ago on account of bereavements. He becomes intoxicated every pay-day, and thinks that the habit is growing upon him; but he is not a drunkard. He received nine hypnotic treatments, beginning on April 1, 1893. The patient reported after the first treatment that his desire for liquor was entirely gone, and that he could not bear the thought of drinking it. He remained perfectly sober so long as he was under my observation. In July he fell beneath an electric car in Omaha and was instantly killed. At the inquest the conductor of the car testified that the patient had been drinking, but was not drunk. His friends in Omaha are, however, positive that he did not drink at all.

CASE XXI.—An American soldier, aged twenty-seven, had been drinking for about five years. He received eight hypnotic treatments, beginning July 15, 1893. He abstained from liquor for about three months, during the greater part of which time he was absent from the post on detached service. On his return he began to drink again—it is thought for convivial reasons—and was soon afterward discharged.

CASE XXII is an American blacksmith, who drinks to excess periodically. He received three hypnotic treatments in July, 1893, after which he went away on business and was unable to continue the treatment. He drank beer occasionally for several weeks after this, but says that he found that "his mind was off it," *i. e.*, that he did not crave it as he formerly did. Since that time he has abstained entirely from all intoxicating drinks and regards himself as permanently cured.

CASE XXIII.—An American, aged thirty-five, a soldier, has been drinking for ten years and has "sprees" lasting a week or more every few months. He was admitted to the hospital on November 25, 1893, suffering from the effects of drink. He was hypnotized on December 1st and received seven treat-

ments on consecutive days and two others subsequently. He has been abstinent since beginning treatment, and states that he feels no desire for liquor.

Excluding Case II, on account of inadequate treatment, Cases V and XVIII, because of the death of the patients, and Case XX, because the result is not known, there remains a series of nineteen cases which may be classified as follows:

1. Remained abstinent to the present time or when last heard from, 8.
2. Relapsed and abstinent after further treatment, hypnotic or "specific," 3.
3. Relapsed after passing out of reach, 2.
4. Relapsed and sought no further treatment, 3.
5. Relapsed and continued to drink, notwithstanding additional treatment, 3.

It may be fairly claimed that all of the patients were sufficiently influenced by the treatment to have become convinced that they could be cured by a continuance of it. It is, therefore, safe to assume for all of the patients in Class 4 what I know to be true of one (Case XIII), that conviviality has pleasures for them which they have found themselves unwilling to forego. The patients in Class 5 (Cases VI, XV, and XVI) were all non-commissioned officers who were induced by their company commanders to submit to the treatment, and, with the exception of Case XVI in the early part of his treatment, were not themselves desirous of help. These men are restricted by their rank to a narrow circle of intimate friends, who are for the most part drinking men, and total abstinence means for them the loss of almost all social pleasures. The conspicuously bad result in their cases shows well the futility of attempting such reform without the hearty coöperation of the subject. Suggestive treatment can only be expected to remove the physical cravings for alcohol. But, unfortunately, after such cravings have disappeared many motives for the indulgence still remain, such as the influence of associates, fondness for excitement and conviviality, and the desire to forget trouble or disgrace.

In estimating the results here reported it should be borne in mind that the frontier is a most unfavorable place for the cure of alcoholism, on account of the almost universal use of alcoholic beverages by the population and the lack of innocent amusements.

I have never failed to hypnotize a patient who sought treatment for alcoholism. Of the 23 cases here reported, 18 were hypnotized on the first attempt, 3 on the second, 1 on the third, and 1 on the fifth.

The method which I generally pursue is as follows: The patient, who is comfortably seated, is directed to fix his gaze and his attention upon some object before him. It is not necessary that this object should be bright, nor that it be placed so near as to strain the accommodation or cause marked convergence of the optic axes. In the meanwhile, standing behind the patient, I stroke his forehead gently and evenly with both hands. In the great majority of cases the patient's eyes close spontaneously in from two to ten minutes. In some cases the patient is on the point of being hypnotized, but the eyes remain open and must be closed before hypnosis is induced. These cases may be recognized by the fixity of the lids. The patient does not wink, or if winking is still performed, the act is incomplete—the upper lid does not fall so as to completely cover the eyeball. A more effectual, but more disagreeable way of hypnotizing, is to sit facing the patient and look him in the eye, the patient being charged to fix his eyes steadily upon one of the eyes of the physician, which are brought within a foot or two of his own. The psychic effect upon the patient is greater than if he were looking at an inanimate object, and his attention is consequently more easily concentrated. The physician relaxes his accommodation to escape the eye-strain which would otherwise be incurred. The eye-muscles of the patient are necessarily strained by this method, but the pain and in a great measure the conjunctival injection may be removed by suggestions during the succeeding hypnosis. Verbal suggestions may advantageously be employed in connection with either of these methods. If the patient is not hypnotized in fifteen minutes it is, as a rule, best not to persist in the attempt to influence him at that sitting. The second attempt will almost always be successful. Hypnosis being induced, suggestions are given to the effect that the patient will have no craving for liquor; that it will be disagreeable to the taste and unpleasant in its effects; that sleep, appetite, and digestion will be good; that nervousness will disappear, etc. It is well to suggest that there will be no nervousness, no pain in the eyes, and no headache upon awaking, also especially in the case of those who are hypnotized with difficulty that there will be no drowsiness.

The ease with which patients fall asleep increases generally at each repetition of the hypnosis within certain limits. That intoxication predisposes to hypnosis is shown, however, by the fact that a patient who has been hypnotized in two minutes while under the influence of liquor, often requires three or four times as many minutes to produce that result after he has become perfectly sober.

The treatments are repeated, if possible, every day for at least a week, after which they are given once a week for a few weeks, then once a month. The number of treatments necessary must be determined separately for each case, as there are great differences in the individual reaction to suggestion. I

have allowed the worst drunkards to continue to drink during the early part of their treatment, with the restriction that they take no more liquor than is necessary to prevent nervousness and sleeplessness. This concession saves the patient some suffering, and the effect upon his imagination is perhaps greater if he is convinced by actual trial that liquor is becoming more and more unpleasant in its taste and its effects. From three to six treatments generally suffice to remove the craving for alcoholic stimulants in those who abstain. In those who continue to drink, the effect of the treatment always manifests itself in a rapid loss of the acquired tolerance for liquor, which becomes more intoxicating and at the same time more disagreeable, until a point is reached, generally after from five to seven treatments, when it appears to the patient that a sudden change takes place in his appetite. He can often state the exact hour when "the whiskey turned on him," as he is apt to express it. This change he considers so profound and permanent that there is often difficulty in inducing him to return for what appears to him unnecessary additional treatment.

It is an interesting fact that, while it is easy to render whiskey repugnant to the senses of the patient, it appears to be impossible to accomplish this in the case of beer by any number of suggestions. The loss of tolerance and the cessation of cravings for alcohol are reached, however, with as great certainty in the one class of drinkers as in the other.

It might be expected that patients would attempt to excuse themselves in case of relapse by alleging the return of irresistible cravings for liquor. This has occurred in none of my cases, except Case XV, under circumstances already detailed. The difficulty is almost always the temptations of conviviality, unwillingness to offend by refusing "treats," and the like. In the least successful cases the first taste of alcohol reawakens the former cravings. The majority resume their old habits more gradually, and the whiskey-drinker will sometimes drink beer for a considerable period without excess. But in all cases the continued indulgence in drink leads certainly and generally speedily to drunkenness. The relapsed drunkard finds that he has no longer the ability to "carry" liquor upon which he once prided himself. If he does not recognize and respect that fact he is in danger of the deepest intoxication.

The evil effects of alcohol upon the nervous system are marked in cases that have been treated by suggestion, and delirium tremens may result from comparatively slight excess. (See Cases V and XIV.) It is perhaps unnecessary to say that this loss of tolerance of alcohol is due simply to the character of the hypnotic suggestions which have been employed. Hypnotism may be used to produce the opposite effect.[1]

Suggestions the effects of which are not intended to persist should be avoided. It is not necessary to attempt to impress the imagination of the patient by varied suggestions the purpose of which simply is to show the power of the physician over him. Nor is it necessary for the treatment of the great majority of cases that the subject be in the so-called "suggestible stage" of hypnosis. Functions which are not directly under the control of the will, such as sleep, peristalsis, the appetites—natural and artificial, pain, the organic sensations, etc., may be influenced by suggestion in any stage of hypnosis from the slightest drowsiness to the deepest sleep. Even a considerable degree of intoxication is no barrier to the success of such suggestion, as I have repeatedly observed. (See especially Case II.)

Hypnotism is not necessarily exhausting to the patient, as has been claimed. On the contrary, if his nervous energy is not wasted by suggestions which produce fatigue or disgust, he feels refreshed upon awaking, as from ordinary sleep. The dangers of hypnotism, as far as they exist elsewhere than in the imagination of its opponents, are due almost always to an improper use of the method Certainly as employed for the cure of alcoholism there are no dangers to be feared from it which are at all comparable with those arising from a continuance in habits of intemperance.
